The **External Jugular Vein** receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of or in front of the *Scalenus anticus* muscle. In the neck it is separated from the Sterno-mastoid by the investing layer of the deep cervical fascia, and is covered by the *Platysma*, the superficial fascia, and the integument. This vein is crossed about its middle by the *superficialis colli* nerve, and its upper half is accompanied by the *auricularis magnus* nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the *sinus*. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.¹

Surgical Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the *Platysma myoides* in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and near its termination, the suprascapular and transverse cervical veins.

¹ The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia, anatomically and experimentally considered, including the Demonstration of Valves in the Veins of the Neck," in the *Edinburgh Medical Journal* for November, 1856.

It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The **Posterior External Jugular Vein** commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **Anterior Jugular Vein** commences near the hyoid bone from the convergence of several superficial veins from the submaxillary region. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 331). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The **Internal Jugular Vein** collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It commences just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 329). At its origin it is somewhat dilated, and this dilatation is called the *sinus*, or *gulf*, of the internal jugular vein. It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid, and then on the outer side of the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein. The internal jugular vein, at its commencement, lies upon the Rectus capitis lateralis, and behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forward between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward, behind or in front of, the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. At its point of junction with the common facial vein it becomes greatly increased in size.

The **lingual veins** commence on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the ranine vein, which is a branch of considerable size commencing below the tip of the tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the facial.

The **pharyngeal vein** commences in a minute plexus, the *pharyngeal*, at the back part and sides of the pharynx, and, after receiving meningeal tributaries and the Vidian and sphenopalatine veins, terminates in the internal jugular. It occasionally opens into the facial, lingual, or superior thyroid vein.

The **superior thyroid vein** commences in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and crico-thyroid veins.

The **middle thyroid vein** collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein.

The **facial and occipital veins** have been described above.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear, in order to prevent septic emboli being carried into the general circulation. This operation has been performed recently in several cases, with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and consequent on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is a danger of a portion of the septic clot being detached and causing septic embolism in the thoracic viscera. If the condition is suspected, the sinus should be at once explored by trephining at a point an inch behind the centre of the external auditory meatus and a quarter of an inch above Reid's base line. The condition of the sinus is then investigated, and if it is found to be thrombosed, the surgeon should at once proceed to ligate the internal jugular vein, by an incision along the anterior border of the sterno-mastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligated in two places and divided between. After the vessel has been secured and divided, the lateral sinus is to be thoroughly cleared out, and by removing the ligature from the upper end of the divided vein, all septic clots removed by syringing from the sinus through the vein. If hemorrhage occurs from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The **Vertebral Vein** commences in the occipital region by numerous small tributaries from the deep muscles at the upper and back part of the neck; these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the foramina in the transverse processes of the cervical vertebræ. This plexus unites at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh, and, uniting, form a single vessel, which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condyloid foramen; muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a *small vein* from the *first intercostal space* which accompanies the superior intercostal artery.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The **posterior vertebral vein** (the **deep cervical**) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis colli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë.

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, which are lined by a more or less complete layer of compact tissue.

The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or *culs-de-sac*, which serve as

reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins and with the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. They are divided into the *frontal*, which opens into the supra-orbital vein by an aperture in the supra-orbital notch; the *anterior temporal*, which is confined chiefly to the frontal bone, and opens into one of the deep temporal veins, after escaping by an aperture in the great wing of the sphenoid;

FIG. 325.—Veins of the Diploë as displayed by the removal of the outer table of the skull.

the *posterior temporal*, which is confined to the parietal bone, and terminates in the lateral sinus by an aperture at the posterior inferior angle of the parietal bone; and the *occipital*, the largest of the four, which is confined to the occipital bone, and opens either into the occipital vein or internally into the lateral sinus or torcular Herophili.

The Cerebral Veins.

The **Cerebral Veins** are remarkable for the extreme thinness of their coats in consequence of the muscular tissue in them being wanting, and for the absence of valves. They may be divided into two sets: the superficial, which are placed on the surface, and the deep veins, which occupy the interior of the organ.

The **Superficial Cerebral Veins** ramify upon the surface of the brain, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, superior, median, and inferior cerebral veins.

The **Superior Cerebral Veins**, eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the great longitudinal fissure, where they receive the *median cerebral veins*; near their termination they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus in the opposite direction to the course of the current of the blood.

The **Median Cerebral Veins** return the blood from the convolutions of the mesial

surface of the corresponding hemisphere; they open into the superior cerebral veins, or occasionally into the inferior longitudinal sinus.

The **Inferior Cerebral Veins** ramify on the lower part of the outer and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the *middle cerebral vein*, commences on the under surface of the temporal lobe, and, running along the fissure of Sylvius, opens into the cavernous sinus. Another large vein, the *great anastomotic vein of Trolard*, commences on the parietal lobe, runs along the horizontal limb of the fissure of Sylvius, and opens into the anterior part of the cavernous sinus under the lesser wing of the sphenoid. Others commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backward.

The **Deep Cerebral, or Ventricular Veins** (*venæ Galeni*), are two in number. They are formed by the union of two veins, the *vena corporis striati*, and the *choroid vein*, on either side. They run backward, parallel with one another, between the layers of the velum interpositum, and pass out of the brain at the great transverse fissure, between the posterior extremity, or *splenium*, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two veins usually unite to form one, the *vena magna Galeni*, before opening into the straight sinus, just before their union they receive the basilar vein.

The *vena corporis striati* commences in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein to form one of the *venæ Galeni*.

The **choroid vein** runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum.

The **Basilar vein** commences at the anterior perforated space at the base of the brain by the union of a small anterior cerebral vein, which courses backward between the anterior lobes of the cerebrum, with the deep Sylvian vein, which descends through the lower part of the Sylvian fissure. It passes backward round the crus cerebri, receiving the inferior striate vein from the corpus striatum, interpeduncular veins from the interpeduncular space, ventricular veins from the middle cornu of the lateral ventricles, and tributaries from the uncinatæ convolution, and enters the vein of Galen just before its junction with the vein of the opposite side.

The **Cerebellar veins** occupy the surface of the cerebellum, and are disposed in three sets, superior, inferior, and lateral. The *superior* pass partly forward and inward, across the superior vermiform process, to terminate in the straight sinus and the *venæ Galeni*, partly outward to the lateral and superior petrosal sinuses. The *inferior cerebellar veins*, of large size, terminate in the lateral, superior petrosal, and occipital sinuses.

The perivascular lymphatics alluded to in the section on General Anatomy are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura Mater.

The sinuses of the dura mater are venous channels, analogous to the veins, their outer coat being formed by the dura mater; their inner, by a continuation of the lining membrane of the veins. They are fourteen in number, and are divided into two sets: 1, those situated at the upper and back part of the skull; 2, those at the base of the skull. The former are—the

Superior Longitudinal Sinus.

Inferior Longitudinal Sinus.

Occipital Sinus.

Straight Sinus.

Lateral Sinuses.

The **Superior Longitudinal Sinus** occupies the attached margin of the falx cerebri. Commencing at the foramen cæcum, through which, in the child, it constantly communicates by a small branch with the veins of the nasal fossæ, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular in form, narrow in front, and gradually increases in size as it passes backward. On examining its inner surface it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (*chordæ Willisii*) are also seen, extending transversely across the inferior angle of the sinus: and, lastly, some small, white, projecting bodies, the *glandulæ Pacchioni*. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina.

The *torcular Herophili*, or *confluence of the sinuses*, is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus**, more correctly described as the *inferior longitudinal vein*, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross branch

FIG. 326.—Vertical section of the skull, showing the sinuses of the dura mater.

with the torcular Herophili. Beside the inferior longitudinal sinus, it receives the venæ Galeni and the superior cerebellar veins. A few transverse bands cross its interior.

The **Lateral Sinuses** are of large size, and are situated in the attached margin of the tentorium cerebelli. They commence at the internal occipital protuberance,

one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. They pass outward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, then curve downward and inward on each side to reach the jugular foramen, where they terminate in the internal jugular vein. Each sinus rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and on the occipital again just before its termination. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. These sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal jugular vein (Fig. 329). They communicate with the veins of the pericranium by means of the mastoid and posterior condyloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins and some veins from the diploë. The *petro-squamous sinus*, when present, runs backward along the junction of the petrous and squamous-temporal, and opens into the lateral sinus.

The **Occipital** is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The sinuses at the base of the skull are—the

Cavernous sinuses.

Superior Petrosal sinuses.

Circular sinus.

Inferior Petrosal sinuses.

Transverse sinus.

The **Cavernous Sinuses** are named from their presenting a reticulated structure, due to their being traversed by numerous interlacing filaments. They are two in number, of irregular form, larger behind than in front, and are placed one on each side

FIG. 327.—Plan showing the relative position of the structures in the right cavernous sinus, viewed from behind.

of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone; they receive anteriorly the ophthalmic vein through the sphenoidal fissure, and open behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division of the fifth nerve. These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavernous sinuses receive some of the cerebral veins, and also a small sinus, the *spheno-parietal*, which extends inward on the under aspect of the lesser wing of the sphenoid; they communicate with the lateral sinuses by means of the superior and inferior petrosal sinuses, and with the facial vein through the ophthalmic vein. They also communicate with each other by means of the circular sinus.

Surgical Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumor in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or they may occur idiopathically from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, swelling, and congestion of the lids and conjunctivæ, and development of a pulsating tumor at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins (see page 605) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The **Ophthalmic Veins** are two in number, superior and inferior.

The *superior ophthalmic vein* connects the angular vein at the inner angle of the orbit with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus.

FIG. 328.—The sinuses at the base of the skull.

The *inferior ophthalmic vein* receives the veins from the floor of the orbit, and either passes out of the orbit through the sphenomaxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or, more frequently, in common with the superior ophthalmic vein.

The **Circular sinus** is formed by two transverse vessels, the *anterior* and *posterior intercavernous sinuses*, which connect together the two cavernous sinuses; the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The **Superior petrosal sinus** is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the

tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **Inferior petrosal sinus** is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital. It commences in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen; the junction of these two sinuses forming the commencement of the internal jugular vein. The inferior petrosal sinus receives the veins from the internal ear and also veins from the medulla, pons, and under surface of the cerebellum.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the fora-

FIG. 329.—Relation of nerves to sinuses in jugular foramen. (Henle.)

men with a meningeal branch of the occipital artery, and between the two are the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see Fig. 329). These sinuses are semicylindrical in form.

The **Transverse Sinus**, or **basilar sinus**, consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins.—The emissary veins are vessels which pass through apertures

in the cranial wall and establish communications between the sinuses inside the skull and the veins external to it. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A vein which passes through the parietal foramen and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condyloid foramen and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein which passes through the posterior condyloid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small vein passing through the foramen of Vesalius connecting the same parts. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein.

FIG. 330.—The superficial veins of the upper extremity.

means of the vein which passes through the foramen cæcum, which is another communication between the intracranial and extracranial circulation which is constantly found in children.

Surgical Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein at the inner angle of the orbit (page 595), and the communication of the veins of the scalp with the diploic veins (page 599). Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus by means of the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by

VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the Upper Extremity are divided into two sets, *superficial* and *deep*.

The **Superficial Veins** are placed immediately beneath the integument between the two layers of superficial fascia.

The **Deep Veins** accompany the arteries, and constitute the *venæ comites* of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial.

The superficial veins of the upper extremity are—the

Superficial veins of the Hand.	Median.
Anterior Ulnar.	Median Cephalic.
Posterior Ulnar.	Median Basilic.
Common Ulnar.	Basilic.
Radial.	Cephalic.

The **Superficial Veins of the Hand and Fingers** are principally situated on the dorsal surface, and form two plexuses, an inner and outer, on the back of the hand. The inner plexus is formed by the veins from the little finger (*vena salvatella*), the ring finger, and the ulnar side of the middle finger; from it the anterior and posterior ulnar veins are derived. The outer plexus is formed by veins from the thumb, the index finger, and radial side of the middle finger; from it the radial vein is derived. These two plexuses communicate on the back of the hand, forming the superficial arch of veins in this situation. The superficial veins from the palm of the hand form a plexus in front of the wrist, from which the median vein is derived.

The **Anterior Ulnar Vein** commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The **Posterior Ulnar Vein** commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the *Abductor minimi digiti* muscle.

The **Common Ulnar** is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** commences from the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. It forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein.

The **Median Vein** ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend of the elbow it receives a branch of communication from the deep veins, and divides into two branches, the median cephalic and median basilic, which diverge from each other as they ascend.

The **Median Cephalic**, usually the smaller of the two, passes outward in the groove between the *Supinator longus* and *Biceps* muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** passes obliquely inward, in the groove between the Biceps and Pronator radii teres, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion (the *bicipital fascia*) which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.¹

Venesection is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arterio-venous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

The **Basilic Vein** is of considerable size, formed by the coalescence of the common ulnar vein with the median basilic. It passes upward along the inner side of the Biceps muscle, pierces the deep fascia a little below the middle of the arm, and, ascending in the course of the brachial artery to the lower border of the tendons of the *Latis-simus dorsi* and *Teres major* muscles, it is continued onward as the axillary vein.

The **Cephalic Vein** courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the *Pectoralis major* and *Deltoid* muscles, lying in the same groove with the descending or humeral branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and crossing the axillary artery, it terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The **Deep Veins of the Upper Extremity** follow the course of the arteries, forming their *venæ comites*. They are generally two in number, one lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two digital veins accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two *venæ comites* which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the *superficialis volæ*, and on the ulnar side terminate in the deep ulnar veins. The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the *venæ comites* of the brachial artery.

The **Interosseous Veins** accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the *venæ comites* of the ulnar artery.

The **Deep Palmar Veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. They communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the *venæ comites* of the radial artery. At the wrist they receive a dorsal and a palmar tributary from the thumb, and unite with the deep radial veins. Accompanying the radial artery, these vessels terminate in the *venæ comites* of the brachial artery.

¹ Cruveilhier says: "Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic."

The **Brachial Veins** are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the Subscapularis, they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **Axillary Vein** is of large size, and is the continuation upward of the basilic vein. It commences at the lower border of the tendons of the *Teres major* and *Latissimus dorsi*, increases in size as it ascends, by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costo-coracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near its termination it receives the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins.

Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always a danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-coracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of glands from the axilla, no sharp cutting instruments should be used after the axillary cavity has been freely exposed, and care should be taken to use no undue force in isolating the glands. Should the vein be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligated above and below.

The **Subclavian Vein**, the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind and above, with the subclavian artery, from which it is separated internally by the *Scalenus anticus* muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the *Scalenus anticus*. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

Tributaries.—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the *Scalenus*, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal jugular the left subclavian vein receives the thoracic duct, while the right subclavian vein receives the right lymphatic duct.

The **Innominate or Brachio-cephalic Veins** (Fig. 331) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **Right Innominate Vein** is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right superior intercostal veins.

trachea, behind the Sterno-thyroid muscles. From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and outward across the innominate artery to open into the right innominate vein, just at its junction with the superior vena cava. These veins receive œsophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their termination in the innominate veins.

The **Superior intercostal veins** (right and left) drain the blood from two or three intercostal spaces below the first. The *right* vein passes downward and inward and opens into the vena azygos major; the *left* runs across the transverse aorta and opens into the left innominate vein. It usually receives the left bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. The *highest intercostal vein*, *i. e.*, from the first space, opens directly into the corresponding vertebral or innominate vein.

The **Superior Vena Cava** receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—*In front*, with the pericardium and process of cervical fascia which is continuous with it: this separates it from the thymus gland and from the sternum; *behind*, with the root of the right lung; on its *right side*, with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **Azygos Veins** connect together the superior and inferior venæ cavæ, taking the place of those vessels in that part of the chest occupied by the heart.

The larger, or *right azygos vein* (vena azygos major), commences opposite the first or second lumbar vertebra by a branch from the right lumbar veins (the *ascending lumbar*); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. Whilst passing through the aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the lower ten intercostal veins of the right side, the upper two or three of these opening first of all into the right superior intercostal vein. It receives the azygos minor veins, several œsophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the three upper intercostal spaces, usually form two trunks, named the left lower and the left upper azygos veins.

The *left lower*, or *smaller azygos vein* (vena azygos minor), commences in the lumbar region by a branch from one of the lumbar veins (*ascending lumbar*) or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, ascending on the left side of the spine as high as the ninth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate

in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some œsophageal and mediastinal veins.

The *left upper azygos vein* varies inversely with the size of the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually three or four in number, and join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or six intercostal space.

Surgical Anatomy.—In obstruction of the inferior vena cava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The *bronchial veins* return the blood from the substance of the lungs; that of the right side opens into the vena azygos major near its termination; that of the left side, into the left superior intercostal vein or left upper azygos vein.

THE SPINAL VEINS.

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column (the *dorsi-spinal veins*).
 2. Those situated in the interior of the spinal canal, between the vertebræ and the theca vertebralis (*meningo-rachidian veins*).
 3. The veins of the bodies of the vertebræ (*venæ basis vertebrarum*).
 4. The veins of the spinal cord (*medulli-spinal*).
1. The **Dorsi-spinal Veins** commence by small branches which receive their

FIG. 332.—Transverse section of a dorsal vertebra, showing the spinal veins.

blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They form a complicated network, which surrounds the spinous processes, the laminae, and the transverse and articular processes of all the vertebræ. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebræ, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina. They terminate by joining the vertebral

veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

2. **The Meningo-rachidian Veins.**—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebræ. They consist of two longitudinal plexuses, one of which runs along the posterior surface of the bodies of the vertebræ (*anterior longitudinal spinal veins*). The other plexus (*posterior longitudinal spinal veins*) is placed on the inner or anterior surface of the laminæ of the vertebræ.

The *Anterior Longitudinal Spinal Veins* consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebræ along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by transverse trunks which pass beneath the ligament, and receive the large *venæ basis vertebrarum* from the interior of the body of each vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of

FIG. 333.—Vertical section of two dorsal vertebræ, showing the spinal veins.

uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The *Posterior Longitudinal Spinal Veins*, smaller than the anterior, are situated one on each side, between the inner surface of the laminæ and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. These veins, by branches which perforate the ligamenta subflava, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins.

3. **The Veins of the Bodies of the Vertebræ** (*venæ basis vertebrarum*) emerge from the foramina on their posterior surface, and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebræ, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part, and open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. **The Veins of the Spinal Cord** (*medulli-spinal*) consist of a minute, tortuous,

venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. These vessels emerge chiefly from the median furrows, and are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and then terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where it joins the other veins from the spinal canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS.

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep, the superficial veins being placed beneath the integument, between the two layers of superficial fascia, the deep veins accompanying the arteries and forming the *venæ comites* of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The **Superficial Veins of the Lower Extremity** are the *internal* or *long saphenous* and the *external* or *short saphenous*.

On the dorsum of the foot is a venous arch situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a plexus on the dorsum of the foot. The arch terminates internally in the long saphenous, externally in a short saphenous vein.

The **internal or long saphenous vein** (Fig. 334) commences at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **external or short saphenous vein** (Fig. 335) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg. Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle.¹ It receives numerous large tributaries from the back part of

¹ Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on *Varicose Disease of the Lower Extremities*, p. 24, where there is also a careful and elaborate description of the branches of the saphena veins.)

the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

FIG. 334.—The internal or long saphenous vein and its branches.

Surgical Anatomy.—The saphena veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than of those in other parts of the body, except perhaps the spermatic and hæmorrhoidal veins. The course of the internal saphenous is in front of the tip of the malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The short saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact. On the Continent the internal saphenous vein as it rests on the tibia just above the malleolus is sometimes selected for venesection.

FIG. 335.—External or short saphenous vein.

The Deep Veins of the Lower

Extremity accompany the arteries and their branches, and are called the *venæ comites* of those vessels.

The external and internal plantar veins unite to form the posterior tibial. They accompany the posterior tibial artery and are joined by the *peroneal veins*.

The anterior tibial veins are formed by a continuation upward of the *venæ comites* of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The **Popliteal Vein** is formed by the junction of the *venæ comites* of the anterior and posterior tibial vessels; it ascends through the popliteal space to the tendinous aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the

heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to its outer side. It receives the sural veins from the Gastrocnemius muscle, the articular veins, and the external saphenous. The valves in this vein are usually four in number.

The **Femoral Vein** accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart's ligament it is joined by the profunda femoris; near its termination it is joined by the internal saphenous vein. The valves in this vein are four or five in number.

The **External Iliac Vein** commences at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one, and sometimes two valves.

The Deep Epigastric Veins.—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The Deep Circumflex Iliac Veins.—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament and terminates in the external iliac vein.

The **Internal Iliac Vein** is formed by the *venæ comites* of the branches of the internal iliac artery, the umbilical arteries of the foetus excepted. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the hæmorrhoidal and vesico-prostatic plexuses in the male, and the uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The **internal pudic veins** (*venæ comites*) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the dorsal vein of the penis, which opens into the prostatic plexus.

The **hæmorrhoidal plexus** surrounds the lower end of the rectum, being formed by the superior hæmorrhoidal veins, tributaries of the inferior mesenteric. It commences as a series of dilated pouches, about twelve in number, which are arranged circularly at the verge of the anus and are connected by transverse branches. From these pouches veins, about six in number, pass upward in a straight direction in the submucous tissue for about three inches; they then pierce the muscular coat and become arranged in a circular manner at right angles to the long axis of the gut, and eventually unite to form the superior hæmorrhoidal vein.

Surgical Anatomy.—The veins of this plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure: the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hæmorrhoidal and portal veins have no valves: the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defecation: they are affected by every form of portal obstruction.

The **vesico-prostatic plexus** surrounds the neck and base of the bladder and prostate gland. It communicates with the hæmorrhoidal plexus behind, and receives the dorsal vein of the penis, which enters the pelvis beneath the subpubic ligament. This plexus is supported upon the sides of the bladder by a reflection of the pelvic fascia. The veins composing it are very liable to become varicose, and often contain hard, earthy concretions, called *phleboliths*.

Surgical Anatomy.—This plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation.

The **dorsal vein of the penis** is a vessel of large size which returns the blood from the body of that organ. At first it consists of two branches, which are contained in the groove on the dorsum of the penis, and it receives veins from the glans penis, the corpus spongiosum, and numerous superficial veins; these unite into a single trunk, which passes between the two parts of the suspensory ligament of the penis, and through an aperture below the subpubic ligament, and divides into two branches, which enter the prostatic plexus.

The **vaginal plexus** surrounds the vagina, being especially developed at the orifice of the canal; it communicates with the vesical plexus in front, and with the hæmorrhoidal plexus behind.

The **uterine plexus** is situated along the sides and superior angles of the uterus, between the layers of the broad ligament, receiving, during pregnancy, large venous canals (the *uterine sinuses*) from the substance of the placenta. The veins composing this plexus anastomose frequently with each other and with the ovarian veins. They are not tortuous like the arteries.

The **Common Iliac Veins** are formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, they terminate upon the intervertebral substance between the fourth and fifth lumbar vertebræ, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The *right common iliac* is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The *left common iliac*, longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **middle sacral veins** accompany the corresponding artery along the front of the sacrum, and join to form a single vein which terminates in the left common iliac vein; occasionally in the angle of junction of the two iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.¹

The **Inferior Vena Cava** returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the fifth lumbar vertebra. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove on its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered for a very short distance by its serous layer, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the *Eustachian*, which is of large size during foetal life.

Relations.—*In front*, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the

¹ See two cases which have been described by Mr. Walsham in the *St. Bartholomew's Hospital Reports*, vols. xvi. and xvii.

posterior surface of the liver, which partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, right semilunar ganglion; on the *left side*, with the aorta.

Peculiarities.—*In Position.*—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart: in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

Tributaries.—It receives in its course the following veins:

Lumbar.	Suprarenal.
Right Spermatic.	Phrenic.
Renal.	Hepatic.

The **lumbar veins**, four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebræ beneath the Psoas magnus, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the *ascending lumbar*. It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **spermatic veins** emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the *spermatic plexus* (*plexus pampiniformis*), which forms the chief mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle. The spermatic veins are provided with valves.¹ The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Surgical Anatomy.—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall.

The **ovarian veins** are analogous to the spermatic in the male; they form a plexus near the ovary and in the broad ligament and Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

¹ Rivington has pointed out that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein (*Journal of Anatomy and Physiology*, vol. vii. p. 163).

The **renal veins** are of large size, and placed in front of the renal arteries.¹ The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the vena cava a little higher than the right.

The **suprarenal veins** are two in number: that on the right side terminates in the vena cava; that on the left side, in the left renal or phrenic vein.

The **phrenic veins** follow the course of the phrenic arteries. The *two superior*, of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary. The *two inferior phrenic veins* follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

The **hepatic veins** commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery: these tributaries, gradually uniting, usually form three large veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right, and another from the left lobe, open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins.

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion (stomach, intestine, and pancreas) and from the spleen. The trunk formed by their union (*vena portæ*) enters the liver and ramifies throughout its substance after the manner of an artery and ends in capillaries, from which the blood is collected into the hepatic veins, which terminate in the inferior vena cava. The branches in this vein are in all cases single, and destitute of valves.

The veins forming the portal system are: the

Superior mesenteric.
Splenic.

Inferior mesenteric.
Gastric.

Cystic.

The **superior mesenteric vein** returns the blood from the small intestines and from the cæcum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portæ. It receives the right gastro-epiploic vein.

The **splenic vein** commences by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portæ. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The **inferior mesenteric vein** returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. It lies to the left of the artery, and ascends beneath the peritoneum in the lumbar region; it passes behind the transverse portion

¹ The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.

of the duodenum and pancreas, and terminates in the splenic vein. Its hæmorrhoidal branches inosculate with those of the internal iliac, and thus establish a communication between the portal and the general venous system.¹

The gastric veins are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former (*pyloric*, Walsham) runs along the lesser cur-

FIG. 336.—Portal vein and its branches.

NOTE.—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

vature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portæ. The latter (*coronary*, Walsham) begins near the pylorus, runs along the lesser curvature of the stomach toward the

¹ Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the œsophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See *Physiological Anatomy*, by Todd and Bowman, 1859, vol. ii. p. 348.)

œsophageal opening, and then passes across the front of the spine from left to right to end in the vena portæ, at a point a little above the junction of the pyloric vein.

The **Portal Vein** is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the head of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the *sinus* of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the common bile duct and the hepatic artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, surrounded by a quantity of loose areolar tissue (*capsule of Glisson*), and placed between the layers of the lesser omentum.

The Cystic Vein.—The vena portæ generally receives the cystic vein, although it sometimes terminates in the right branch of the vena portæ.

The portal vein divides, in the substance of the liver, like an artery, and its minute ramifications end in capillaries, from which the blood is carried to the inferior vena cava by the hepatic veins; these veins also collect the blood which has been brought to the liver by the hepatic artery. It will therefore be seen that the blood which is carried to the liver by the portal vein passes through two sets of capillary vessels, viz.: (1) the capillaries in the stomach, intestine, pancreas, and spleen, and (2) the capillaries of the portal vein in the liver.

THE CARDIAC VEINS.

The veins which return the blood from the substance of the heart are: the

Great cardiac vein.

Anterior cardiac veins.

Posterior cardiac vein.

Right or small coronary vein.

Left cardiac veins.

Coronary sinus.

Venæ Thebesii.

The **Great Cardiac Vein** (sometimes called the *Coronary vein*) is a vessel of considerable size, which commences at the apex of the heart, and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the left extremity of the coronary sinus, its aperture being guarded by two valves. It receives, in its course, tributaries from both ventricles, but especially the left, and also from the left auricle; one of these, ascending along the thick margin of the left ventricle, is of considerable size. The vessels joining it are provided with valves.

The **Posterior Cardiac Vein** (sometimes called the *Middle cardiac vein*) commences by small tributaries, at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the coronary sinus, its orifice being guarded by a valve. It receives the veins from the posterior surface of both ventricles.

The **Left Cardiac Veins** are three or four small vessels, which collect the blood from the posterior surface of the left ventricle, and open into the lower border of the coronary sinus.

The **Anterior Cardiac Veins** are three or four small vessels, which collect the blood from the anterior surface of the right ventricle. One of these (the *vein of Galen*), larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The **Right or Small Coronary Vein** runs along the groove between the right auricle and ventricle, to open into the right extremity of the coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The **Coronary Sinus** is that portion of the anterior or great cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives the veins enumerated above, and an *oblique vein* from the back part of the left auricle, the remnant of the obliterated left Cuvierian duct of the fœtus, described by Mr. Marshall. The great coronary sinus terminates in the right auricle, between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the *Thebesian valve*. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The **Venæ Thebesii** (*venæ cordis minimæ*) are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices (*foramina Thebesii*) on the inner surface of the right auricle.

THE LYMPHATIC SYSTEM.

THE Lymphatic System includes not only the lymphatic vessels and the glands through which they pass, but also the *lacteal* or *chyliferous vessels*. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that they contain a milk-white fluid, the *chyle*, during the process of digestion, and convey it into the blood through the thoracic duct.

The lymphatics have derived their name from the appearance of the fluid contained in their interior (*lymph*, water). They are also called *absorbents*, from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation.

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them. They retain a nearly uniform size, being interrupted at intervals by constrictions, which give them a knotted or beaded appearance. These constrictions are due to the presence of valves in their interior. Lymphatics have been found in nearly every texture and organ of the body which contain blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

The lymphatics are arranged into a superficial and deep set. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue throughout the whole length of the gastro-pulmonary and genito-urinary tracts, and in the subserous tissue in the cranial, thoracic, and abdominal cavities. The method of their origin will be described later, along with the other details of their minute anatomy. Here it will be sufficient to say that a plexiform network of minute lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge, which pass either to a neighboring gland or to join some larger lymphatic trunk. The deep lymphatics, fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

The lymphatic or absorbent glands, named also *conglobate glands*, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. In size they vary from a hemp-seed to an almond, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these bodies in their passage to the thoracic and lymphatic ducts. A lymphatic or lacteal vessel, previous to

entering a gland, divides into several small branches, which are named *afferent vessels*. As they enter their external coat becomes continuous with the capsule of the gland, and the vessels, much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the lymph-sinuses of the gland. From these sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single *efferent vessel*, which, on emerging from the gland, is again invested with an external coat. (Further details on the minute anatomy of the lymphatic vessels and glands will be found in the section on General Anatomy.)

FIG. 337.—The thoracic and right lymphatic duct.

THE THORACIC DUCT.

The thoracic duct (Fig. 337) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the *receptaculum chyli* (reservoir or cistern of Pecquet), which is situated upon the front of the body of the second lumbar vertebra, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. It ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra it inclines toward the left

side, and ascends behind the arch of the aorta on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left

subclavian vein at its angle of junction with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in size to the diameter of a goosequill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous in its course, and constricted at intervals so as to present a varicose appearance. The thoracic duct not unfrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has numerous valves throughout its whole course, but they are more numerous in the upper than in the lower part: at its termination it is provided with a pair of valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

Tributaries.—The thoracic duct, at its commencement, receives four or five large trunks from the abdominal lymphatic glands, and also the trunk of the lacteal vessels. Within the thorax it is joined by the lymphatic vessels from the left half of the wall of the thoracic cavity, the lymphatics from the sternal and intercostal glands, those of the left lung, left side of the heart, trachea, and œsophagus; and, just before its termination, it receives the lymphatics of the left side of the head and neck and left upper extremity.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The *internal coat* consists of a single layer of flattened lanceolate-shaped endothelial cells with serrated borders; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. The *middle coat* consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminæ of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal and intermixed with elastic fibres. The *external coat* is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The **Right Lymphatic Duct** is a short trunk, about half an inch in length and a line or a line and a half in diameter. It terminates in the right subclavian vein at its angle of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung and right side of the heart, and from part of the convex surface of the liver.

LYMPHATICS OF THE HEAD, FACE, AND NECK.

The **Lymphatic Glands of the Head** (Fig. 338) are arranged in the following groups: (1) The *occipital*, one or two in number, placed at the back of the head, close to the occipital artery. (2) The *posterior auricular* or *mastoid*, usually two in number, situated on the insertion of the Sterno-mastoid to the mastoid process. Both these sets of glands are affected in cutaneous eruptions and other diseases of the scalp. (3) The *parotid* or *pre-auricular*, some of which are superficial to, and others are imbedded in, the substance of the parotid gland. (4) The *buccal*, one or more, placed on the surface of the Buccinator muscle. (5) The *internal maxillary*, beneath the ramus of the jaw. (6) The *lingual*, two or three in number, lying on the Hyo-glossus and Genio-hyo-glossus. (7) The *retro-pharyngeal*, lying one on each side of the middle line in front of the Rectus capitis anticus major.

The **lymphatic vessels of the scalp** are divided into an *anterior* and a *posterior set*, which follow the course of the temporal and occipital vessels. The *temporal* accompany the temporal artery in front of the ear, to the parotid lymphatic glands, from which they proceed to the lymphatic glands of the neck. The *occipital* follow the course of the occipital artery, descend to

the occipital and posterior auricular lymphatic glands, and finally join the cervical glands.

The **Lymphatic Vessels of the Face** are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the face** are more numerous than those of the head, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running

FIG. 338.—The superficial lymphatics and glands of the head, face, and neck.

with the facial vein, pass through the buccal glands on the surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The latter receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The **lymphatic vessels of the cranium** consist of two sets, the *meningeal* and *cerebral*. The *meningeal lymphatics* accompany the meningeal vessels, escape through foramina at the base of the skull, and join the deep cervical lymphatic glands. The *cerebral lymphatics* are described by Eshmann as being situated between the arachnoid and pia mater, as well as in the choroid plexuses of the lateral ventricles; they accompany the trunks of the carotid and vertebral arteries, and probably pass through foramina at the base of the skull to terminate in the deep cervical glands. They have not at present been demonstrated in the dura mater or in the substance of the brain.

The lymphatics of the orbit and of the temporal and zygomatic fossæ run with

the branches of the internal maxillary artery to the maxillary glands, and afterward to the deep cervical.

The lymphatics of the nose can be injected from the subdural and subarachnoid spaces. They terminate in the retro-pharyngeal and supra-hyoid glands. The lymphatics of the tongue chiefly accompany the ranine vein first to the lingual glands and from these to the deep cervical. Those from the anterior part of the tongue and floor of the mouth pierce the Mylo-hyoid muscles and so reach the submaxillary glands. From the upper part of the pharynx the lymphatics pass to the retro-pharyngeal glands; from the lower part, to the deep cervical glands. From the larynx two sets of vessels arise: an upper, piercing the thyro-hyoid

FIG. 339.—The deep lymphatics and glands of the neck and thorax.

membrane and joining the superior set of deep glands; and a lower, perforating the crico-thyroid membrane to join the lower set of deep cervical glands. The lymphatics of the thyroid body accompany the superior and inferior thyroid arteries, and open partly into the upper and partly into the lower set of deep cervical glands.

The **Lymphatic Glands of the Neck** are divided into two sets, *superficial* and *deep*.

The **superficial cervical glands** may be arranged in three sets: (1) The *submaxillary*, eight to ten in number, situated beneath the body of the lower jaw in the submaxillary triangle; (2) *suprahyoid*, one or two in number, situated

in the middle line of the neck, between the anterior bellies of the two digastric muscles; and (3) *cervical*, placed in the course of the external jugular vein between the Platysma and deep fascia. They are most numerous at the root of the neck, in the triangular interval between the clavicle, the Sterno-mastoid, and the Trapezius, where they are continuous with the axillary glands. A few small glands are also found on the front and sides of the larynx.

The **deep cervical glands** (Fig. 339) are numerous and of large size; they form a chain along the sheath of the carotid artery and internal jugular vein, lying by the side of the pharynx, œsophagus, and trachea, and extending from the base of the skull to the thorax, where they communicate with the lymphatic glands in that cavity. They are subdivided into two sets: an *upper*, ten to twenty in number, situated about the bifurcation of the common carotid and along the upper part of the internal jugular vein; and a *lower*, ten to fifteen in number, clustered around the lower part of the internal jugular vein, and extending outward into the supra-clavicular fossa, where they are continuous with the axillary glands. Internally, this set is continuous with the mediastinal glands.

The **superficial and deep cervical lymphatic vessels** are a continuation of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, œsophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite into a single trunk, which terminates, on the left side, in the thoracic duct; on the right side, in the right lymphatic duct.

Surgical Anatomy.—The cervical glands are very frequently the seat of tuberculous disease. This condition is most usually set up by some lesion in those parts from which they receive their lymph. This excites some inflammation, which subsequently takes on a tuberculous character. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. The following table is extracted from Mr. Treves's work on *Scrofula and its Gland Diseases*:

Scalp.—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

Skin of face and neck = submaxillary, parotid, and superficial cervical glands.

External ear = superficial cervical glands.

Lower lip = submaxillary and suprahyoid glands.

Buccal cavity = submaxillary and upper set of deep cervical glands.

Gums of lower jaw = submaxillary glands.

Tongue.—Anterior portion = suprahyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

Tonsils and palate = upper set of deep cervical glands.

Pharynx.—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

Larynx, orbit, and roof of mouth = upper set of deep cervical glands.

Nasal fossæ = retro-pharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossæ enter the parotid glands.

LYMPHATICS OF THE UPPER EXTREMITY.

The **Lymphatic Glands of the Upper Extremity** (Fig. 340) are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic glands** are few and of small size. There are occasionally two or three in front of the elbow, and one or two above the internal condyle of the humerus, near the basilic vein, while one or two may be found lying beside the cephalic vein between the Pectoralis major and Deltoid muscles.

The **deep lymphatic glands** are few in number, and are subdivided into those in the forearm, the arm, and the axilla. In the *forearm* a few small ones are occasionally found in the course of the radial and ulnar vessels. In the *arm* there is a chain of small glands along the inner side of the brachial artery. One, sometimes two, fairly constant glands are situated a little above and in front of the inner condyle of the humerus. In the *axilla* they are of large size, and

usually ten or twelve in number. A chain of these glands surrounds the axillary vessels, imbedded in a quantity of loose areolar tissue; they receive the lymphatic vessels from the arm; others are dispersed in the areolar tissue of the axilla; the remainder are arranged in two series, a small chain running along the lower border of the Pectoralis major, receiving the lymphatics from the front of the chest and mamma; and others are placed along the lower margin of the posterior wall of the axilla, which receive the lymphatics from the integument of the back.

FIG. 340.—The superficial lymphatics and glands of the upper extremity.

Two or three subclavian or infra-clavicular lymphatic glands are placed immediately beneath the clavicle; it is through these that the axillary and deep cervical glands communicate with each other. The efferent vessels from the axillary glands may be from one to three or four in number. They accompany the subclavian vein into the neck, and end, on the right side, by joining the right lymphatic duct, on the left side by opening into the thoracic duct.

Surgical Anatomy.—In malignant diseases, tumors, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the

front and side of the abdomen, or the hand, forearm, and arm, the axillary glands are liable to be found enlarged.

The **lymphatic vessels of the upper extremity** are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the upper extremity** commence on the fingers, two vessels running along either side of each finger, one on the palmar and the other on the dorsal surface. Those on the palmar surface form an arch in the palm of the hand, from which are derived two sets of vessels, which pass up the forearm, taking the course of the subcutaneous veins. The lymphatics from the dorsal surface of the fingers form a plexus on the back of the hand, and, winding around the inner and outer borders of the forearm, unite with those in front. Those from the inner border of the hand accompany the ulnar veins along the inner side of the forearm to the bend of the elbow, where they are joined by some lymphatics from the outer side of the forearm: they then follow the course of the basilic vein, communicate with the glands immediately above the elbow, and terminate in the axillary glands, joining with the deep lymphatics. The superficial lymphatics from the outer and back part of the hand accompany the radial veins to the bend of the elbow. They are less numerous than the preceding. At the bend of the elbow the greater number join the basilic group; the rest ascend with the cephalic vein on the outer side of the arm, some crossing the upper part of the Biceps obliquely, to terminate in the axillary glands, whilst one or two accompany the cephalic vein in the cellular interval between the Pectoralis major and Deltoid, and enter the subclavian lymphatic glands.

The **deep lymphatic vessels of the upper extremity** accompany the deep blood-vessels. In the forearm they consist of four sets, corresponding with the radial, ulnar, and interosseous arteries; they pass through the glands occasionally found in the course of those vessels, and communicate at intervals with the superficial lymphatics. In their course upward some of them pass through the glands which lie upon the brachial artery; they then enter the axillary and subclavian glands, and at the root of the neck terminate on the left side in the thoracic duct, and on the right side in the right lymphatic duct.

LYMPHATICS OF THE LOWER EXTREMITY.

The **Lymphatic Glands of the Lower Extremity** are divided into two sets, *superficial* and *deep*. The superficial are confined to the inguinal region, forming the *superficial inguinal lymphatic glands*.

The **superficial inguinal lymphatic glands**, placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper *oblique* set, disposed irregularly along Poupert's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior *vertical* set, two to five in number, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receives the superficial lymphatic vessels from the lower extremity. Leaf¹ figures some of the efferent vessels from these glands as terminating directly in the veins of this region.

Surgical Anatomy.—These glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer scroti, in abscess in the perinæum, or in any other diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The **deep lymphatic glands** are the anterior tibial, popliteal, deep inguinal, gluteal, and ischiatic.

¹ *The Surgical Anatomy of the Lymphatic Glands*, 1898.

The **anterior tibial gland** is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation.

The **popliteal glands**, four or five in number, are of small size; they surround the popliteal vessels, imbedded in the cellular tissue and fat of the popliteal space.

The **deep inguinal glands** are placed beneath the deep fascia around the femoral artery and vein. They are of small size, and communicate with the superficial inguinal glands through the saphenous opening.

The **gluteal and ischiatic glands** are placed, the former above, the latter below, the Piriformis muscle, resting on their corresponding vessels as they pass through the great sacro-sciatic foramen.

The **Lymphatic Vessels of the Lower Extremity**, like the veins, may be divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels** are placed beneath the integument in the superficial fascia, and are divisible into two groups: an internal group, which follow the course of the internal saphenous vein; and an external group, which accompany the external saphenous. The *internal group*, the larger, commence on the inner side and dorsum of the foot; they pass, some in front and some behind, the inner ankle, run up the leg with the internal saphenous vein, pass with it behind the inner condyle of the femur, and accompany it to the groin, where they terminate in the group of superficial inguinal lymphatic glands which surround the saphenous opening. Some of the efferent vessels from these glands pierce the cribriform fascia and sheath of the femoral vessels, and terminate in a lymphatic gland contained in the femoral canal, thus establishing a communication between the lymphatics of the lower extremity and those of the trunk; others pierce the fascia lata and join the deep inguinal glands. The *external group* arise from the outer side of the foot, ascend in front of the leg, and, just below the knee, cross the tibia from without inward, to join the lymphatics on the inner side of the thigh. Others commence on the outer side of the foot, pass behind the outer malleolus,

FIG. 341.—The superficial lymphatics and glands of the lower extremity.

and accompany the external saphenous vein along the back of the leg, where they enter the popliteal glands.

The deep lymphatic vessels of the lower extremity are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these, the vessels pass beneath Poupart's ligament and communicate with the chain of glands surrounding the external iliac vessels.

The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

LYMPHATICS OF THE PELVIS AND ABDOMEN.

The Lymphatic Glands in the Pelvis are the external iliac, the internal iliac, and the sacral. Those of the abdomen are the lumbar and coeliac glands.

The external iliac glands form an uninterrupted chain round the external iliac vessels, three being placed round the commencement of the vessels just behind the crural arch. They communicate below with the deep inguinal lymphatic glands, and above with the lumbar glands.

The internal iliac glands surround the internal iliac vessels; they receive the lymphatic vessels corresponding to the branches of the internal iliac artery, and communicate with the lumbar glands.

The sacral glands occupy the sides of the anterior surface of the sacrum, some being situated in the meso-rectal fold. These and the internal iliac glands are affected in malignant disease of the bladder, rectum, or uterus.

The lumbar glands are very numerous; they are situated on the front of the lumbar vertebræ, surrounding the common iliac vessels, the aorta, and vena cava; they receive the lymphatic vessels from the lower extremities and pelvis, as well as from the testes and some of the abdominal viscera: the efferent vessels from these glands unite into a few large trunks, which, with the lacteals, form the commencement of the thoracic duct. In addition to these there are a few small *lateral lumbar glands* which lie between the transverse processes of the vertebræ, behind the Psoas muscle, and receive lymphatics from the back. In some cases of malignant disease these glands become enormously enlarged, completely surrounding the aorta and vena cava, and occasionally greatly contracting the calibre of those vessels. In all cases of malignant disease of the testes and in malignant disease of the lower limb, before any operation is attempted, careful examination of the abdomen should be made, in order to ascertain if any enlargement exists; and if any should be detected, all operative measures should be avoided as fruitless.

The Coeliac Glands, nearly twenty in number, surround the coeliac axis and lie in front of the aorta near the origin of that vessel. They receive the lymphatic vessels from a large part of the liver, from the spleen, pancreas, and stomach. Their efferent vessels join the lacteals from the intestine and open into the receptaculum chyli.

The Lymphatic Vessels of the Abdomen and Pelvis may be divided into two sets, *superficial* and *deep*.

The superficial lymphatic vessels of the walls of the abdomen and pelvis follow the course of the superficial blood-vessels. Those derived from the integument of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands; a deeper set accompany the deep epigastric vessels, and communicate with the external iliac glands. The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind round the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superior group

of the superficial inguinal glands; the greater number, however, run backward along with the ilio-lumbar and lumbar vessels, to join the lateral lumbar glands.

The superficial lymphatic vessels of the gluteal region turn horizontally round the outer side of the nates, and join the superficial inguinal glands.

The superficial lymphatic vessels of the scrotum and perinæum follow the course of the external pudic vessels, and terminate in the superficial inguinal glands.

FIG. 342.—The deep lymphatic vessels and glands of the abdomen and pelvis.

The superficial lymphatic vessels of the penis occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the skin covering the glans penis; they all converge to the upper chain of the superficial inguinal glands. The deep lymphatic vessels of the penis follow the course of the internal pudic vessels, and join the internal iliac glands.

In the female the lymphatic vessels of the mucous membrane of the labia, nymphæ, and clitoris terminate in the upper chain of the inguinal glands.

The deep lymphatic vessels of the abdomen and pelvis take the course of the principal blood-vessels. Those of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lumbar lymphatics.

The efferent vessels from the inguinal glands enter the pelvis beneath Poupart's ligament, where they lie in close relation with the femoral vein; they then pass through the chain of glands surrounding the external iliac vessels, and finally terminate in the lumbar glands. They receive the deep epigastric and circumflex iliac lymphatics.

The lymphatic vessels of the bladder arise from the entire surface of the organ;¹ the greater number run beneath the peritoneum on its posterior surface, and, after passing through the lymphatic glands in that situation, join with the lymphatics from the prostate and vesiculæ seminales, and enter the internal iliac glands.

The lymphatic vessels of the rectum are of large size; after passing through some small glands that lie upon its outer wall and in the meso-rectum they pass to the sacral glands.

The lymphatic vessels of the uterus consist of two sets, *superficial* and *deep*, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri, together with those from the greater part of the vagina, enter the internal iliac and sacral glands; those from the body and fundus of the uterus pass outward in the broad ligaments, and, being joined by the lymphatics from the ovaries, broad ligaments, and Fallopian tubes, ascend with the ovarian vessels to open into the lumbar glands; the lymphatics from the lower part of the vagina join those of the external genitals and pass to the superficial inguinal glands. In the unimpregnated uterus they are small, but during gestation they become very greatly enlarged.

The lymphatic vessels of the testicle consist of two sets, *superficial* and *deep*: the former commence on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate into the lumbar glands; hence the enlargement of these glands in malignant disease of the testis.

The lymphatic vessels of the kidney arise on the surface, and also in the interior of the organ; they join at the hilum, and, after receiving the lymphatic vessels from the ureter and suprarenal capsules, open into the lumbar glands.

The lymphatic vessels of the liver are divisible into two sets, *superficial* and *deep*. The former arise in the subperitoneal areolar tissue over the entire surface of the organ. Those on the convex surface may be divided into four groups: 1. Those which pass from behind forward, consisting of three or four branches, which ascend in the falciform ligament and unite to form a single trunk, which passes up between the fibres of the Diaphragm, behind the ensiform cartilage, to enter the anterior mediastinal glands, and finally ascends to the root of the neck, to terminate in the right lymphatic duct. 2. Another group, which also incline from behind forward, are reflected over the anterior margin of the liver to its under surface, and from thence pass along the longitudinal fissure to the glands in the gastro-hepatic omentum. 3. A third group incline outward to the right lateral ligament, and, uniting into one or two large trunks, pierce the Diaphragm, and run along its upper surface to enter the anterior mediastinal glands, or, instead of entering the thorax, turn inward across the crus of the Diaphragm and open into the commencement of the thoracic duct. 4. The fourth group incline outward from the surface of the left lobe of the liver to the left lateral ligament, pierce the Diaphragm, and, passing forward, terminate in the glands in the anterior mediastinum.

¹ Curnow states that they are confined to the base of the organ.

The *superficial lymphatics on the under surface of the liver* are divided into three sets: 1. Those on the right side of the gall-bladder enter the lumbar glands. 2. Those surrounding the gall-bladder form a remarkable plexus; they accompany the hepatic vessels, and open into the glands in the gastro-hepatic omentum. 3. Those on the left of the gall-bladder pass to the œsophageal glands and to the glands which are situated along the lesser curvature of the stomach.

The *deep lymphatics* accompany the branches of the portal vein and the hepatic artery and duct through the substance of the liver; passing out at the transverse fissure, they enter the lymphatic glands along the lesser curvature of the stomach and behind the pancreas, or join with one of the lacteal vessels previous to its termination in the thoracic duct.

The **lymphatic glands of the stomach** are of small size; they are placed along the upper part of the lesser and toward the pyloric end of the greater curvature.

The **lymphatic vessels of the stomach** consist of two sets, *superficial* and *deep*; the former originating in the subserous, and the latter in the submucous coat. They follow the course of the blood-vessels, and may consequently be arranged into three groups. The *first group* accompany the gastric vessels along the lesser curvature to the cardiac orifice, receiving branches from both surfaces of the organ, and pass to the cœliac glands. The *second group* pass from the great end of the stomach, accompanying the vasa brevia, and enter the splenic lymphatic glands. The *third group* run along the greater curvature with the right gastro-epiploic vessels toward the pylorus, and, receiving the lymphatics from the upper part of the duodenum, terminate in the cœliac glands.

The **lymphatic glands of the spleen** occupy the hilum. Its *lymphatic vessels* consist of two sets, *superficial* and *deep*; the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the blood-vessels, passing through a series of small glands, and, after receiving the lymphatics from the pancreas, ultimately pass into the cœliac glands.

The *lymphatics of the pancreas* also enter the cœliac glands.

THE LYMPHATIC SYSTEM OF THE INTESTINES.

The **lymphatic glands of the small intestine** are placed between the layers of the mesentery, occupying the meshes formed by the superior mesenteric vessels, and hence called *mesenteric glands*. They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small almond.¹ These glands are most numerous and largest above, the glands of the jejunum, being more numerous than those of the ileum. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines.

The **lymphatic glands of the large intestine** are much less numerous than the mesenteric glands; they are situated along the vascular arches formed by the arteries previous to their distribution, and even sometimes upon the intestine itself. They are fewest in number along the transverse colon, where they form an uninterrupted chain with the mesenteric glands.

The **lymphatic vessels of the small intestine** are called *lacteals*, from the milk-white fluid they usually contain: they consist of two sets, *superficial* and *deep*, the former lie between the layers of the muscular coat and between the muscular and peritoneal coats, taking a longitudinal course along the outer side of the intestine; the latter occupy the submucous tissue, and course transversely round the intestine, accompanied by the branches of the mesenteric vessels; they pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate separately in the receptaculum chyli; frequently, however, they first unite to form a single large trunk, termed the *intestinal lymphatic trunk*.

The **lymphatic vessels of the large intestine** consist of two sets: those of the

¹ Leaf (*op. cit.*) says it is very common to find not more than forty or fifty.

cæcum, ascending and transverse colon, which, after passing through their proper glands, enter the mesenteric glands; and those of the descending colon, sigmoid flexure, and rectum, which pass to the lumbar glands.

THE LYMPHATICS OF THE THORAX.

The **Lymphatic Glands of the Thoracic Wall** are the intercostal, internal mammary, anterior mediastinal, and posterior mediastinal.

The **intercostal glands** are small, and situated on each side of the spine, near the costo-vertebral articulations; they vary from one to three in each space.

The **sternal or internal mammary glands** are placed at the anterior extremity of each intercostal space, by the side of the internal mammary vessels.

The **anterior mediastinal glands** are placed in the loose areolar tissue of the anterior mediastinum, some lying upon the Diaphragm in front of the pericardium, and others round the great vessels at the base of the heart.

The **posterior mediastinal glands** are situated in the areolar tissue in the posterior mediastinum, forming a continuous chain by the side of the aorta and œsophagus; they communicate on each side with the intercostal, below with the lumbar, and above with the deep cervical glands.

The **Superficial Lymphatic Vessels of the Front of the Thorax** run across the great Pectoral muscle, and those on the back part of this cavity lie upon the Trapezius and Latissimus dorsi; they all converge to the axillary glands. The lymphatics from the greater part of the mammary gland pass outward to the lower border of the Pectoralis major muscle, where they enter a chain of small glands situated in the axillary space along the lower border of its anterior boundary. Some few lymphatics from the inner side of the mammary gland pass through the intercostal spaces to reach the anterior mediastinal glands.

The **Deep Lymphatic Vessels of the Thoracic Wall** are the intercostal, internal mammary, and diaphragmatic.

The **intercostal lymphatic vessels** follow the course of the intercostal vessels, receiving lymphatics from the intercostal muscles and pleura; they pass backward to the spine, and unite with lymphatics from the back part of the thorax and spinal canal. After traversing the intercostal glands, they pass down the spine and terminate in the thoracic duct.

The **internal mammary lymphatic vessels** follow the course of the internal mammary vessels; they commence in the muscles of the abdomen above the umbilicus, communicating with the epigastric lymphatics, ascend between the fibres of the Diaphragm at its attachment to the ensiform appendix, and in their course behind the costal cartilages are joined by the intercostal lymphatics; they terminate on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The **lymphatic vessels of the Diaphragm** follow the course of their corresponding vessels, and terminate, some in front in the anterior mediastinal and internal mammary glands, some behind, in the intercostal and posterior mediastinal lymphatics.

The **Lymphatic Glands of the Viscera of the Thorax** are the bronchial glands.

The **bronchial glands** are situated round the bifurcation of the trachea and roots of the lungs. They are ten or twelve in number, the largest being placed opposite the bifurcation of the trachea, the smallest round the bronchi and their primary divisions for some little distance within the substance of the lungs. In infancy they present the same appearance as lymphatic glands in other situations; in the adult they assume a brownish tinge, and in old age a deep black color. Occasionally they become sufficiently enlarged to compress and narrow the canal of the bronchi, and they are often the seat of tuberculous deposits.

The **superior mediastinal or cardiac glands** lie in front of the transverse aorta

and left innominate vein; this group consists of numerous large glands. They receive the lymph from the pericardium, heart, and thymus gland.

The **lymphatic vessels of the lung** consist of two sets, *superficial* and *deep*: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi: they both terminate at the root of the lungs in the bronchial glands. The efferent vessels from these glands, two or three in number, ascend upon the trachea to the root of the neck, traverse the tracheal and œsophageal glands, and terminate on the left side in the thoracic duct and on the right side in the right lymphatic duct.

The **cardiac lymphatic vessels** consist of two sets, *superficial* and *deep*: the former arise in the subserous areolar tissue of the surface, and the latter in the deeper tissues of the heart. They follow the course of the coronary vessels: those of the right side unite into a trunk at the root of the aorta, which, ascending across the arch of that vessel, communicates with one or more of the cardiac glands, and passes backward to the trachea, upon which it ascends, to terminate at the root of the neck in the right lymphatic duct. Those of the left side unite into a single vessel at the base of the heart, which, passing along the pulmonary artery and traversing some glands at the root of the aorta, ascends on the trachea to terminate in the thoracic duct.

The **thymic lymphatic vessels** arise from the under surface of the thymus gland, and enter the superior mediastinal glands, from which they emerge as two vessels: these terminate, one on each side, in the corresponding internal jugular vein.

The **lymphatic vessels of the œsophagus** form a plexus round that tube, traverse the glands in the posterior mediastinum, and, after communicating with the pulmonary lymphatic vessels near the roots of the lungs, terminate in the thoracic duct.

THE NERVOUS SYSTEM.

THE Nervous System is composed: 1. Of a series of large centres of nerve-matter, called, collectively, the *cerebro-spinal centres* or *cerebro-spinal axis*. 2. Of smaller centres, termed *ganglia*. 3. Of nerves connected either with the cerebro-spinal axis or the ganglia. And 4. Of certain modifications of the peripheral terminations of the nerves forming the organs of the external senses.

The Cerebro-spinal axis consists of the brain or encephalon and the spinal cord, which are contained within the skull and spinal canal. The brain and its membranes will be first considered, and then the spinal cord and its coverings.

THE MEMBRANES OF THE BRAIN.

Dissection.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about an inch above the margin of the orbit, and extending, behind, to a little above the level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.

The membranes of the brain are: the dura mater, arachnoid membrane, and pia mater.

The Dura Mater.

The **Dura Mater** is a thick and dense inelastic fibrous membrane which lines the interior of the skull. Its outer surface is rough and fibrillated, and adheres closely to the inner surface of the bones, forming their internal periosteum, this adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth and lined by a layer of endothelium. It sends four processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen cæcum; it sends a series of tubular prolongations round the filaments of the olfactory nerves as they pass through the cribriform plate, and also round the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process into the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condyloid foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. In certain situations, as already mentioned (page 594), the fibrous layers of this membrane separate, to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the *glandulæ Pacchioni*.

Structure.—The dura mater consists of white fibrous tissue with connective-tissue cells and elastic fibres arranged in flattened laminæ which are imperfectly separated by lacunar spaces and blood-vessels into two layers, *endosteal* and *meningeal*. The endosteal layer is the internal periosteum for the cranial bones,

and contains the blood-vessels for their supply. At the margin of the foramen magnum it becomes continuous with the periosteum lining the spinal canal. The meningeal or supporting layer is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes: these cells were formerly regarded as belonging to the arachnoid membrane. By its reduplication the meningeal layer forms the *falx cerebri*, the tentorium and *falx cerebelli*, and the *diaphragma sellæ*. The two layers are connected by fibres which intersect each other obliquely.

Its *arteries* are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. In the middle fossa are the middle and small meningeal branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis cranii, branches from the internal carotid, and a recurrent branch from the lachrymal. In the posterior fossa are meningeal branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal, from the vertebral; occasionally meningeal branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condyloid foramen, and a branch from the middle meningeal.

The *veins*, which return the blood from the dura mater, and partly from the bones, anastomose with the diploic veins. These vessels terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein; above they communicate with the superior longitudinal sinus. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of ampullæ termed *venous lacunæ*. These are found on each side of the superior longitudinal sinus, especially near its middle portion, and are often invaginated by Pacchionian bodies; they also exist near the lateral and straight sinuses. They communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The *nerves* of the dura mater are filaments from the Gasserian ganglion, from the ophthalmic, superior maxillary, inferior maxillary, vagus, and hypoglossal nerves, and from the sympathetic.

Processes of the Dura Mater.—The processes of the dura mater, sent inward into the cavity of the skull, are four in number: the *falx cerebri*, the tentorium cerebelli, the *falx cerebelli*, and the *diaphragma sellæ*.

The *falx cerebri*, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull, in the middle line, as far back as the internal occipital protuberance; it contains the superior longitudinal sinus. Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus.

The *tentorium cerebelli* is an arched lamina of dura mater, elevated in the middle and inclining downward toward the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses the lateral sinuses; in front, to the superior margin of the petrous portion of the temporal bone on either side, enclosing the superior petrosal sinuses; and at the apex of this bone the free or internal border and the attached or external border meet, and, crossing one another, are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the *falx cerebri* is

attached, the straight sinus being placed at their point of junction. Its anterior border is free and concave, and bounds a large oval opening for the transmission of the crura cerebri.

The *falx cerebelli* is a small triangular process of dura mater received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The *diaphragma sellæ* is a horizontal process formed by a reduplication of the meningeal layer of the dura mater. It forms a small circular fold, which constitutes a roof for the sella turcica. This almost completely covers the pituitary body, presenting merely a small central opening for the infundibulum to pass through.

The Arachnoid Membrane.

The arachnoid (*ἀράχνη εἶδος*, like a spider's web), so named for its extreme thinness, is a delicate membrane which envelops the brain, lying between the pia mater internally and the dura mater externally; from this latter membrane it is separated by a space, the *subdural space*.

It invests the brain loosely, being separated from direct contact with the cerebral substance by the pia mater, and a quantity of loose areolar tissue, the *subarachnoidean*. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the anterior lobes, and extends across between the two temporal lobes so as to leave a considerable interval between it and the brain, the *anterior subarachnoidean space* (Cisterna pontis); it is in contact with the pons and under surface of the cerebellum; but between the hemispheres of the cerebellum and the medulla oblongata another considerable interval is left between it and the brain, called the *posterior subarachnoidean space* (Cisterna magna). These two spaces communicate together across the crura cerebelli. Other smaller cisternæ are found in various positions; and all communicate freely with one another. The arachnoid membrane surrounds the nerves which arise from the brain, and encloses them in loose sheaths as far as their point of exit from the skull.

The *subarachnoid space* is the interval between the arachnoid and pia mater. It is not, properly speaking, a *space*, for it is occupied everywhere by a spongy tissue consisting of trabeculæ of delicate connective tissue, which pass from the pia mater to the arachnoid, and in the meshes of which the subarachnoid fluid is contained. This so-called space is small on the surface of the hemispheres; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger, where it forms the Cisternæ pontis et magna mentioned above. In addition to these two large spaces, a third is formed on the upper surface of the corpus callosum, for the arachnoid stretches across from one cerebral hemisphere to the other immediately beneath the free border of the falx cerebri, and thus leaves a space in which the anterior cerebral arteries are contained. Another space is found in the fissure of Sylvius, for the arachnoid stretches across from the anterior to the middle lobe of the brain, without dipping down to the bottom of the fissure, and in this space the middle cerebral artery ramifies. The subarachnoid space communicates with the general ventricular cavity of the brain by means of three openings: one of these is in the middle line at the inferior boundary of the fourth ventricle, where an opening in the pia-matral covering of this cavity, the *foramen of Magendie*, exists and permits the passage of fluid from the one space to the other. The other two communications are at the extremities of the lateral recesses of the fourth ventricle, behind the upper roots of the glosso-pharyngeal nerves; they are named

the *foramina of Key and Retzius*. It is stated by Merkel that the lateral ventricles also communicate with the subarachnoid space at the apices of their descending horns.

The subdural space also contains fluid; this is, however, small in quantity compared with the cerebro-spinal fluid and is probably of the nature of lymph.

The *cerebro-spinal fluid* fills up the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres, and to prevent the effects of concussions communicated from without.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor division of the fifth, the facial, and the spinal accessory nerves, are found in the arachnoid.

Glandulæ Pacchioni or Arachnoid Villi.

The *glandulæ Pacchioni* are numerous small whitish granulations usually collected into clusters of variable size, which are found in the following situations: 1. Upon the outer surface of the *dura mater*, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the *dura mater*. 3. In the superior longitudinal sinus. 4. On the *pia mater*, near the margin of the hemispheres.

These bodies are not glandular in structure, but simply enlarged normal villi of the arachnoid. In their growth they appear to perforate the *dura mater*, and when of large size they cause absorption of the bone, and come to be lodged in pits or depressions on the inner table of the skull. Their manner of growth is as follows: at an early period they project through minute holes in the inner layer of the *dura mater*, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the *dura mater* before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the *dura mater* and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies; and through their coverings filters into the superior longitudinal sinus. They are supposed to be the means by which excess of cerebro-spinal fluid is got rid of, when its quantity is increased above normal.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the seventh year; and from this period they increase in number as age advances. Occasionally they are wanting.

The Pia Mater.

The *pia mater* is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminæ, and is prolonged into the interior, forming the *velum interpositum* and choroid plexuses of the lateral and fourth ventricles. Upon the surfaces of the hemispheres, where it covers the gray matter of the convolutions, it is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral

substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the gray substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia mater of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upward over the medulla it is seen to preserve these characters. At the upper border of the medulla it is prolonged over the lower half of the fourth ventricle, forming a covering for it (*tela choroidea inferior*) before it is reflected on to the under surface of the cerebellum.

According to Fohmann and Arnold, this membrane contains numerous lymphatic vessels. Its nerves are derived from the sympathetic, and also from the third, fifth, sixth, facial, glosso-pharyngeal, pneumogastric, and spinal accessory. They accompany the branches of the arteries.

THE BRAIN.

GENERAL CONSIDERATIONS AND DIVISIONS.

The *encephalon* or brain is that portion of the cerebro-spinal axis which is contained in the cavity of the cranium. For purposes of description it may be divided into five parts, as follows: (1) the two cerebral hemispheres; (2) the inter-brain; (3) the mid-brain; (4) the pons Varolii and cerebellum; and (5) the medulla oblongata. If the student will refer to the section on the Development of the Brain he will find that these five portions correspond fairly accurately to the five secondary cerebral vesicles, of which the brain at an early period of embryonal life consisted: the prosencephalon, or *first* vesicle, by means of a protrusion from its front part on either side, forms the cerebral hemispheres and the lateral ventricles; the remainder of the prosencephalon, together with the *second* vesicle, the thalamencephalon, form the inter-brain and third ventricle; the *third* vesicle, the mesencephalon, forms the mid-brain, or that portion which connects the inter-brain and hemispheres above with the pons Varolii below, and the cavity of the vesicle forms the aqueduct of Sylvius, or *iter a tertio ad quartum ventriculum*; the *fourth* vesicle, the epencephalon, becomes the future pons Varolii and cerebellum, and its cavity forms the upper half of the fourth ventricle; and, finally, the *fifth* vesicle, the melencephalon, develops into the medulla oblongata, and its cavity forms the lower half of the fourth ventricle. It will thus be seen that the five divisions of the encephalon mentioned above correspond to the five secondary cerebral vesicles, with the exception of the first two, which together form the cerebral hemispheres and the inter-brain. In consequence of this these two portions of the brain are sometimes grouped together as the *cerebrum*.

I. The Hemispheres of the Brain.

General Considerations.—The two hemispheres constitute the largest portion of the encephalon, and, together with the parts derived from the thalamencephalon, form what is called by some writers the *fore-brain*. They occupy the whole of the vault of the skull, and consist of a central cavity, in either hemisphere, surrounded by exceedingly thick and convoluted walls of nervous tissue. The under surface or base of the cerebrum is of an irregular form, resting in front on the anterior and middle fossæ of the skull and behind upon the tentorium cerebelli. The upper surface is of an ovoid form, broader behind than in front, convex in general outline, and divided into two lateral halves or hemispheres, right and left, by the *great longitudinal fissure*, which extends throughout the entire length of the cerebrum in the middle line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the *corpus callosum*, which connects the two hemispheres together.

The Surface of the Cerebrum.—Each hemisphere presents an outer convex surface, filling the concavity of the corresponding half of the vault of the cranium;

an inner, flattened surface, which is vertical and directed toward the corresponding surface of the opposite hemisphere (the two forming the sides of the longitudinal fissure); and an under surface or base, of an irregular form, which rests in front on the anterior and middle fossæ of the base of the skull, and behind upon the tentorium cerebelli. The hemispheres are composed of an outer stratum of gray matter, called the *cortical substance*. It is thrown into a number of creases or infoldings, which are termed *fissures* and *sulci*, and these separate the surface into a number of irregular eminences, named *convolutions* or *gyri*.

The infoldings or creases are of two kinds, *fissures* and *sulci*. The fissures are of large size, and appear early in foetal life; they are few in number, nearly constant in their arrangement, and are produced by infoldings of the entire thickness

FIG. 343.—Upper surface of the brain, the arachnoid having been removed.

of the wall of the prosencephalon, producing corresponding elevations in the interior of the ventricle, and hence are termed *complete fissures*. They comprise (a) the hippocampal, or dentate fissure; (b) the anterior part of the calcarine fissure; (c) the collateral fissure. The *sulci* are more numerous; they are superficial depressions of the gray matter, which is folded inward and only indents the central white substance. They produce no corresponding elevations in the interior of the ventricle, and are therefore spoken of as *incomplete fissures*. They are fairly constant in their arrangement, and have received names indicative of their position and direction, but at the same time vary, within certain limits, in different individuals. They are similar, without being absolutely identical, on the two sides of the brain. It therefore follows that the gyri or convolutions which lie between these sulci are fairly constant in their general arrangement.

The number and extent of the convolutions, as well as the depth of the intervening sulci, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as one ascends from the lowest mammalia up to man, where they present a most complex arrangement. Again, in the child, at birth, before the intellectual faculties are exercised, the convolutions are simpler, and the sulci between them shallower, than in the adult. In old age, when the mental faculties have diminished in activity, they become less prominently marked. By their arrangement the convolutions are adapted to increase the amount of gray matter without occupying much additional space, while they also afford a greater extent of surface for the termination of white fibres in gray matter.

It will be convenient, in the first instance, to describe the fissure which separates the two hemispheres from each other, and those which divide each hemisphere into its larger divisions.

The Longitudinal Fissure (Fig. 343).—This great fissure separates the cerebrum into two hemispheres, and reaches from the front to the back of the organ : it contains a vertical process of the dura mater, the *falx cerebri* (page 640). In front and behind it extends from the top to the bottom of the cerebrum, and completely sepa-

FIG. 344.—Fissures and lobes on the external surface of the cerebral hemispheres.

rates the two hemispheres, but its middle portion only separates the hemispheres for about half their vertical extent, the floor of this part of the fissure being formed by the great central white commissure, the *corpus callosum*, which connects the two hemispheres together.

The remaining fissures are situated in one or other of the two hemispheres, with the exception of the transverse fissure, one-half of which is contained in each hemisphere.

Sylvian Fissure (Fig. 344).—This fissure is a well-marked cleft on the base and side of the hemisphere. Starting at the base of the brain in a depression, the *vallecula Sylvii*, in which is situated the anterior perforated space, it passes outward to the external surface of the hemisphere. It here gives off a short *anterior*

limb, which passes forward, and a short *ascending limb*, which passes upward into the inferior frontal convolution. It is then continued backward as the *horizontal limb*, which terminates by an upward inflexion in the parietal lobe. It occupies the middle third of the lateral surface of the hemisphere.

The **Fissure of Rolando** is situated about the middle of the outer surface of the hemisphere, and, coursing obliquely downward and forward, divides the surface of the hemisphere into approximately equal parts. It commences at or near the longitudinal fissure, a little behind its mid-point, and runs sinuously downward and forward, to terminate a little above the horizontal limb of the fissure of Sylvius, and about half an inch behind the ascending limb of the same fissure. It forms two chief curves: the upper or *superior genu* is concave forward and upward, while the lower or *inferior genu* has its concavity directed backward.

The **parieto-occipital fissure** is only seen to a slight extent on the outer surface of the hemisphere, being situated for the most part on its mesial aspect. The portion on the outer surface is called the *external parieto-occipital fissure*, to distinguish it from the part continued on to the internal surface, which is termed the *internal parieto-occipital fissure*. The external parieto-occipital fissure commences about midway between the posterior extremity or occipital pole of the brain and the fissure of Rolando, and runs downward and outward for about an inch.

These three fissures divide the external surface of the hemisphere into four lobes: the *frontal*, the *parietal*, the *occipital*, and the *temporal*. To these must be added (1) the central lobe, or island of Reil, which is situated deeply in the Sylvian fissure, and (2) the olfactory lobe, which is found at the base of the brain and was formerly described under the name of the olfactory nerve.

The Lobes on the External Surface.—The lobes on the external surface have received their names from the bones of the skull with which they are most nearly in relation, but it must be borne in mind that they do not correspond in shape or limit with the bone after which they are named. The division is, moreover, to a certain extent artificial, as will be seen from the following description. If a line is drawn in continuation of the external parieto-occipital fissure downward and outward to the lower border of the hemisphere, it will impinge on a slight notch, the *pre-occipital notch*, and if a second line is prolonged backward from the horizontal part of the fissure of Sylvius to join the first, the division of the outer surface of the hemisphere into four lobes will be accomplished (Fig. 344). The portion in front of the fissure of Rolando is the *frontal* lobe; that behind the fissure of Rolando and above the fissure of Sylvius is the *parietal* lobe; the portion behind the parieto-occipital fissure and its continuation is the *occipital* lobe; and the part below the fissure of Sylvius and in front of the occipital lobe is the *temporal* lobe.

The Fissures and Lobes of the Mesial and Tentorial Surfaces.—The mesial surface of the cerebrum can only be fully viewed by dividing the corpus callosum and the structures beneath it longitudinally in the middle line; in order to expose the tentorial surface, the pons Varolii, cerebellum, and medulla must be removed, by division of the crus cerebri on either side. When this has been done, a section such as is represented in Fig. 345 will be shown. The parts in the centre, below the corpus callosum, belong to the interior of the brain, and will be disregarded for the present, while the lobes and fissures of the remaining portion of the hemisphere are considered. The fissures are five in number, in addition to a small part of the fissure of Sylvius, the commencement of which is seen, separating the frontal and temporal lobes. These fissures are named the *calloso-marginal*, the *internal parieto-occipital*, the *calcarine*, the *collateral*, and the *dentate* or *hippocampal*.

The **calloso-marginal fissure** commences below the anterior extremity of the corpus callosum; it at first runs forward and upward, parallel with the rostrum of the corpus callosum, and, winding round in front of the genu of that body, it continues from before backward, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it ascends to reach the upper margin

of the hemisphere, a short distance behind the superior extremity of the fissure of Rolando.

The **internal parieto-occipital** extends in an oblique direction downward and forward to join the calcarine fissure, on a level with the hinder end of the corpus callosum.

The **calcarine fissure** commences, usually by two branches, close to the posterior extremity of the hemisphere. These soon unite, and the fissure runs nearly horizontally forward, and is joined by the parieto-occipital fissure, and continues as far as the posterior extremity of the corpus callosum, a little below the level of which it terminates. Its anterior part causes the prominence in the interior of the brain, known as the *hippocampus minor* or *calcar avis*.

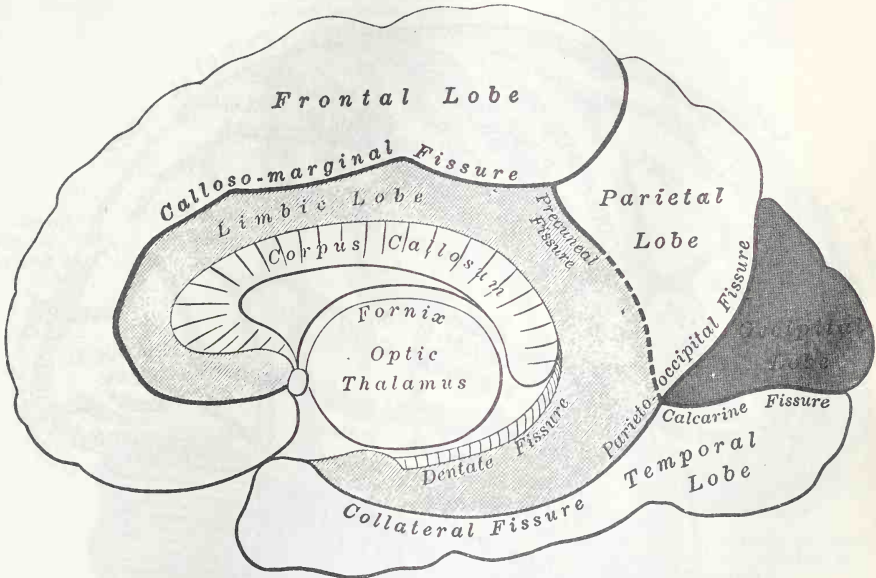

FIG. 345.—Fissures and lobes on the internal surface of the cerebral hemispheres.

The **collateral fissure** is situated on the tentorial surface, below and external to the preceding, being separated from it by the sub-collateral or uncinat gyrus. It runs forward, from the posterior extremity of the brain, nearly as far as the tip of the temporal lobe. It lies below the posterior and descending horns of the lateral ventricle, and its middle part causes the prominence in the interior of the brain, known as the *eminentia collateralis*.

The **dentate** or **hippocampal fissure** commences immediately behind the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the hippocampal gyrus. It causes the prominence of the hippocampus major in the descending horn of the lateral ventricle. In addition to these fissures, which are constant, there is frequently an irregular broken fissure, which appears to be a continuation backward of the posterior part of the calloso-marginal fissure, before it ascends to reach the upper edge of the hemisphere. This has been termed the *post-limbic fissure*. These fissures map off portions of the internal and tentorial surfaces of the hemispheres, which form parts of the lobes found on the external surface. That portion which lies in front and above the calloso-marginal fissure belongs almost entirely to the frontal lobe; its posterior extremity, which extends for a short distance behind the upper end of the fissure of Rolando, forms a small part of the parietal lobe; that portion which lies above the internal parieto-occipital fissure and behind the calloso-marginal fissure forms a part of the parietal lobe; that between the parieto-occipital fissure above and the calcarine fissure below is a portion of the occipital lobe; and all the region below the calcarine

fissure behind and the collateral fissure in front belongs to the temporal lobe. The remainder of the mesial and tentorial surfaces of the hemisphere constitute what Broca termed the *limbic lobe*, which is subsequently referred to (page 652).

The surface of the hemisphere has thus been divided into its different parts, viz.: the frontal, the parietal, the occipital, the temporal, the limbic, the olfactory lobes, and the island of Reil. Each of these lobes is further subdivided into convolutions or gyri by smaller fissures, which, though less constant in their arrangement than the fissures already described, have a fairly definite course.

1. **The Frontal Lobe.**—On its *external* surface the frontal lobe presents three sulci, which divide it into four convolutions (Fig. 346). The *precentral sulcus* runs upward through this lobe, parallel to the lower half of the fissure of

FIG. 346.—Convolutions and sulci on the external surface of the cerebral hemisphere.

Rolando. It is frequently broken or interrupted by annectant gyri. It limits a convolution, which lies between it and the fissure of Rolando, and which is called the *ascending frontal convolution*. From it two sulci, the *superior* and *inferior frontal*, run forward and downward, and divide the remainder of the outer surface of the lobe into three parallel principal convolutions, named respectively the *superior*, *middle*, and *inferior frontal convolutions*.

The *ascending frontal convolution* is a simple convolution, bounded in front by the precentral sulcus, behind by the fissure of Rolando, and extending from the upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below.

The *superior frontal convolution* is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the greater part of the marginal convolution, and in front on to the orbital surface, forming the internal orbital convolution. It is usually more or less completely subdivided into two by an antero-posterior

sulcus, the *sulcus frontalis mesialis* of Cunningham, which, however, is frequently interrupted and broken into several parts by bridging convolutions.

The *middle frontal convolution* is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus on to the orbital surface of the lobe, where it forms the anterior orbital convolution. The middle frontal convolution is frequently subdivided into two by a sagittally directed sulcus, the *sulcus frontalis medius* of Eberstaller.

The *inferior frontal convolution* is situated below the inferior frontal sulcus, and extends forward from the lower part of the precentral sulcus, on to the under surface of the lobe, where it forms the posterior orbital convolution. The inferior frontal convolution is subdivided by the anterior and ascending limbs of the fissure of Sylvius into three parts, viz.: (1) *anterior* or *pars orbitalis*, below the

FIG. 347.—Convolutions and sulci on the under surface of the anterior lobe.

anterior limb of the fissure; (2) *middle* or *pars triangularis* ("cap" of Broca), between the two limbs; and (3) *posterior* or *pars basalis*, behind the ascending limb.

The left inferior frontal convolution is, as a rule, more highly developed than the right, and is named the *convolution of Broca*, from the fact that in 1861 Broca discovered that it was the centre for language.

The *under surface* of the frontal lobe rests on the orbital plate of the frontal bone, and is sometimes named the *orbital lobe* (Fig. 347). It is divided into three convolutions by a well-marked sulcus, the *orbital* or *tri-radiate sulcus*. These are named, from their position, the *internal*, *anterior*, and *posterior orbital convolutions*, and are the continuations respectively of the superior, middle, and inferior frontal convolutions of the external surface. The internal orbital convolution presents a well-marked antero-posterior groove or sulcus, the *olfactory sulcus*, for the olfactory

tract; and the portion internal to this is named the *gyrus rectus*, and is continuous with the marginal gyrus, presently to be described. The *mesial* or *internal surface* of the frontal lobe is occupied by a single curved convolution, which from its situation is termed the *marginal gyrus* (Fig. 348). It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the mesial surface of the orbital lobe, where it is continuous with the internal orbital convolution; it then ascends, and runs backward to the point where the callosomarginal fissure turns upward to reach the superior border of the hemisphere. An oval portion at the posterior part of this convolution is sometimes marked off by a vertical fissure, and is distinguished as the *paracentral gyrus*, because it is continuous with the convolutions in front and behind the central fissure or fissure of Rolando.

2. **The Parietal Lobe.**—On its external surface the parietal lobe presents for examination two sulci and three convolutions.

FIG. 348.—Convolutions and sulci on the internal surface of cerebral hemispheres.

The *intra-parietal sulcus* commences close to the horizontal limb of the fissure of Sylvius, about midway between the fissure of Rolando and the upturned extremity of the fissure of Sylvius. It first runs upward parallel to and behind the lower half of the fissure of Rolando, and then turns backward, extending nearly to the termination of the external parieto-occipital fissure, where it sometimes becomes continuous with the superior occipital sulcus. The ascending portion of this sulcus separates off a convolution, the *ascending parietal*, which lies between it and the fissure of Rolando, while the horizontal portion divides the remainder of the external surface of the parietal lobe into two other convolutions, the *superior* and *inferior parietal*.

The *post-central sulcus* is a slightly marked groove, which is sometimes a branch of the intra-parietal sulcus, being given off where the ascending portion of this sulcus turns backward. It lies parallel to and behind the upper part of the fissure of Rolando, and separates the ascending from the superior parietal convolution.¹

¹ Professor Cunningham describes these two sulci, the intra-parietal and post-central, somewhat differently. He regards them as both belonging to the intra-parietal sulcus, which he divides into three parts: the ascending portion of the intra-parietal, as described above, he terms the *ramus verticalis inferior*; the horizontal portion as the *ramus horizontalis*; while the post-central sulcus he denominates the *ramus verticalis superior*. He states that considerable variability is exhibited in the relation to each other of these different parts of the intra-parietal sulcus, but that the one in which the three parts of the sulcus are confluent is by far the most constant condition. Sometimes, however,

The *ascending parietal convolution* is bounded in front by the fissure of Rolando, behind by the ascending portion of the intra-parietal sulcus and by the post-central sulcus. It extends from the great longitudinal fissure above to the horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also, sometimes, above the termination of the fissure of Rolando.

The *superior parietal convolution* is bounded in front by the post-central sulcus, which lies between it and the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is bounded by the external parieto-occipital fissure, below the termination of which it is joined to the occipital lobe by a narrow convolution, the *first annectant gyrus*; below, it is separated from the inferior parietal convolution by the horizontal portion of the intra-parietal sulcus; and above, it is continuous on the inner surface of the hemisphere with the quadrate lobe.

The *inferior parietal convolution* is that portion of the parietal lobe which is situated between the ascending portion of the intra-parietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is divided into two convolutions by an indistinct groove. One, the *supra-marginal*, lies behind the ascending part of the intra-parietal sulcus and above the horizontal limb of the fissure of Sylvius, over the extremity of which it arches. It is connected in front with the ascending parietal convolution below the intra-parietal sulcus, and behind with the superior temporal convolution round the posterior extremity of the fissure of Sylvius. The other, the *angular*, is united anteriorly with the foregoing, while posteriorly it is continuous with the middle temporal convolution by a process which curves round the superior temporal or parallel sulcus. It is connected with the occipital lobe by the *second annectant gyrus*.

The *internal or mesial surface* of the parietal lobe is continuous with the external surface over the upper edge of the hemisphere. It is of small size, and forms one square-shaped convolution, which from its shape is termed the *quadrate lobe*. From its situation above the cuneate lobe it is sometimes named *precuneus*.

3. The Occipital Lobe.—The occipital lobe is divided on its *external surface* into three convolutions by two indistinct sulci, the *superior* and *middle occipital sulci*. They are directed backward across the lobe, being frequently small and ill marked; the superior is sometimes continuous with the horizontal portion of the intra-parietal sulcus.

The *superior occipital convolution* is situated above the superior sulcus, and is connected to the superior parietal convolution by the *first annectant gyrus*.

The *middle occipital convolution* is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the *second annectant gyrus*, and to the middle temporal convolution by the *third annectant gyrus*.

The *inferior occipital convolution* is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal convolution on the under surface of the hemisphere by an inconstant sulcus, the *inferior occipital sulcus*. It is connected to the inferior temporal convolution by the *fourth annectant gyrus*.

The *internal or mesial surface* of the occipital lobe presents a triangular convolution, which is known as the *cuneus* or *cuneate lobule*. It is situated between the internal parieto-occipital and calcarine fissures, which, as already mentioned, meet some distance behind the posterior extremity of the corpus callosum.

the three parts of the sulcus may be separate, or the ramus horizontalis confluent with the ramus verticalis inferior, the ramus verticalis superior remaining separate; or, again, the vertical limbs may be confluent and the horizontal limb separate; or, finally, the ramus horizontalis may be joined to the lower end of the ramus verticalis superior, while the lower vertical ramus is separate. The prolongation of the intra-parietal sulcus into the occipital lobe, which sometimes exists, he calls the *ramus occipitalis*. In the majority of cases, however, the occipital ramus is separated from the main portion of the intra-parietal sulcus by a superficial or deep bridging convolution. (*Journal of Anatomy and Physiology*, vol. xxiv., part ii., p. 135.)

4. The **temporal lobe**, sometimes called the temporo-sphenoidal lobe, presents an outer and an inferior surface. The *outer surface* is subdivided by two fissures, named respectively the first and second temporal sulci. The *first temporal sulcus* is well marked, and runs from before backward through the temporal lobe parallel with, but some little distance below, the horizontal limb of the fissure of Sylvius, and hence is often termed the *parallel sulcus*. The *second temporal sulcus* takes the same direction as the first, but is situated at a lower level, and is often interrupted by one or more bridging convolutions. These two sulci subdivide this surface of the temporal lobe into three convolutions. The *first or superior temporal convolution* is situated between the horizontal limb of the fissure of Sylvius and the first temporal sulcus, and is continuous behind with the supra-marginal convolution. The *second or middle temporal convolution* lies between the first and second temporal sulci, and is continued behind into the angular and middle occipital convolutions. The *third or inferior temporal convolution* is placed below the second temporal sulcus: it is connected posteriorly with the inferior occipital convolution, and is also prolonged on to the under or tentorial surface of the temporal lobe, where it is limited internally by the third temporal sulcus, about to be described.

The inferior or tentorial surface presents two fissures, viz.: the third temporal sulcus and the collateral fissure—the latter of which has already been described (page 647). The *third temporal sulcus* extends from near the occipital pole behind, to near the anterior extremity of the temporal lobe in front, but is, however, frequently subdivided by bridging gyri. The convolutions on the inferior surface are (1) the *fourth temporal or subcollateral convolution* (sometimes called the *external occipito-temporal*), situated between the third temporal sulcus and the collateral fissure; and (2) the *subcalcarine convolution or lingual lobule*, lying between the calcarine fissure above and the posterior part of the collateral fissure below and continuous in front with the hippocampal convolution, the latter forming part of the limbic lobe.¹

The **central lobe or island of Reil** (Fig. 349) lies deeply in the Sylvian fissure, and can only be seen when the lips of that fissure are widely separated, since it is overlapped and hidden by the convolutions which bound the fissure. These convolutions are termed the *opercula of the insula*; they are separated from each other by the three limbs of the Sylvian fissure, and named the orbital, frontal, fronto-parietal, and temporal opercula. It is almost surrounded by a deep *limiting sulcus*, which separates it from the frontal, parietal, and temporal lobes. When the opercula have been removed, the insula presents the form of a triangular eminence; its apex is directed downward and inward toward the anterior perforated space, and is continuous in front with the posterior orbital convolution and behind with the hippocampal convolution. It is divided into a *pre-central* and a *post-central* lobe by the *sulcus centralis*, which runs backward and upward from the apex of the insula. The pre-central lobe is further subdivided by shallow sulci into three or four short convolutions, the *gyri breves*, while the post-central lobe is named the *gyrus longus* and is often bifurcated at its upper extremity. The gray matter of the insula is continuous with that of the different opercula, while its mesial surface corresponds with the lenticular nucleus of the corpus striatum.

Limbic Lobe.—The term limbic lobe (*grande lobe limbique*) was introduced by Broca in 1878, and under it he included two convolutions, viz., the callosal and hippocampal, which together arch round the corpus callosum and the hippocampal fissure. These he separated on the morphological ground that they are well developed in animals possessing a keen sense of smell (osmatic

¹ It will be seen from this description that the tentorial surface of the occipital lobe is regarded as forming part of the same surface as the temporal lobe. The boundary between the occipital and temporal lobes on the tentorial surface is purely artificial, and if represented by a line drawn upward and inward from the pre-occipital notch, would cut both the subcollateral and subcalcarine gyri.

animals), such as the dog and fox. To the lobe thus defined the following parts must be added, viz.: the laminæ of the septum lucidum, together with the fornix and its fimbriæ, which may be regarded as forming an inner or deep arch; the peduncles and longitudinal striæ of the corpus callosum, together with the gyrus dentatus, which form a middle arch, while the outer arch is constituted by the callosal and hippocampal convolutions: the first two arches are separated from each other by the corpus callosum.

Convolutions of the Limbic Lobe.—(1) The *callosal convolution*, *gyrus fornicatus*, or *gyrus cinguli* is an arch-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like fissure, the *callosal fissure*. It commences below the rostrum of the corpus callosum, curves round in front of the genu, extends along the upper surface of the body, and finally turns downward behind the splenium, where it is connected by a narrow isthmus with the gyrus hippocampi. It is separated from the marginal convolution by the calloso-marginal sulcus, from the quadrate lobe by the post-limbic sulcus, and from the subcalcarine convolution by the calcarine fissure.

(2) The *hippocampal convolution* (*gyrus hippocampi*) is bounded above by the hippocampal or dentate fissure, and below by the anterior part of the collateral

FIG. 349.—The Island of Reil. Left side. The overlapping parts of the hemisphere have been removed. (Dalton.) 1, 2, 3, gyri breves; 4, 5, gyrus longus, bifurcated at its upper extremity.

fissure. Behind, it is continuous superiorly, through the isthmus, with the callosal convolution, and inferiorly with the subcalcarine or lingual convolution. Its anterior extremity is recurved in the form of a hook, and is named the *uncus*. Running in the substance of the callosal and hippocampal convolutions, and connecting them together, is a tract of arched fibres, named the *cingulum*. The outer root of the olfactory tract passes into the anterior extremity of the hippocampal convolution, and the inner root into the commencement of the callosal convolution, so that these two convolutions, with the addition of the olfactory tract, present a racquet-like appearance—the olfactory tract constituting the handle and the two convolutions the circumference of the blade.

(3) The *dentate convolution* (formerly named the *dentate fascia*) is situated above the gyrus hippocampi, from which it is separated by the hippocampal or dentate fissure. It is covered by the fimbria, and is a narrow, elongated convolution, the free surface of which presents a notched or toothed appearance, hence its name. Posteriorly it is prolonged as a delicate lamina, the *fasciola cinerea*, around the splenium of the corpus callosum, and becomes continuous on the upper surface of that body with its mesial and lateral longitudinal striæ. Anteriorly it is prolonged into the notch produced by the recurving of the uncus, where it forms a sharp curve; from here it can be traced as a delicate band (*band of Giacomini*) over the uncus, on the outer surface of which it is lost.

The remaining structures which contribute to the formation of the limbic lobe will be subsequently described.

The olfactory lobe is situated on the under surface of the frontal lobe. It is rudimentary in man and some other mammals, but in vertebrates generally it is well developed, and consists of a distinct extension of the cerebral hemisphere, enclosing a portion of the anterior horn of the lateral ventricle. In man it is long and slender, and may be described as consisting of two parts, the *anterior* and *posterior olfactory lobules*.

The *anterior olfactory lobule* is made up of: (1) the olfactory bulb; (2) the olfactory tract; (3) the trigonum olfactorium; and (4) the area of Broca.

FIG. 350.—Base of the brain.

(1) The *olfactory bulb* is an oval mass of a reddish-gray color, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity of the olfactory tract. Its under surface receives the olfactory nerves, which pass upward through the cribriform plate from the olfactory region of the nose. Its minute structure will be subsequently described.

(2) The *olfactory tract* is a band of white matter, triangular on section, the apex being directed upward. It lies in the olfactory sulcus on the under surface of the frontal lobe. Traced backward, it is seen to divide into two roots, an outer and an inner. The *outer root* passes across the outer part of the anterior perforated space to the nucleus amygdalæ and the anterior part of the gyrus hippocampi. The *inner root* turns sharply inward, and ends partly in Broca's area and partly in

the callosal convolution; in other words, the inner root is continuous with one extremity and the outer root with the other extremity of the limbic lobe.

(3) The *trigonum olfactorium* is situated between the diverging roots of the olfactory tract, and is sometimes described at the *middle* or *gray root* of the tract. It is part of an area of gray matter, which forms the base of the anterior olfactory lobule; another portion of it is termed (4) the *area of Broca*; and a third portion, of no special significance, is situated external to the outer root of the olfactory tract. This area of gray matter is bounded internally and posteriorly by a fissure (*fissura prima*) which separates it from the peduncle of the corpus callosum and from the posterior olfactory lobule. The area of Broca is continuous with the gyrus fornicatus.

The *posterior olfactory lobule* or *anterior perforated space* is marked off from the anterior lobule by the fissura prima, and is situated at the commencement of the fissure of Sylvius. Internally, it is bounded by the peduncle of the corpus callosum, and is continuous with the lamina cinerea. Posteriorly it is bounded by the optic tract, and it is partially concealed by the temporal lobe which overlaps it. It has received the name of anterior perforated space from its being perforated by numerous openings, which transmit blood-vessels to the interior of the brain, and it corresponds to the under surface of the lenticular nucleus and part of the claustrum.

Under Surface or Base of the Encephalon (Fig. 350).—Having considered the surface of the hemispheres, the student should direct his attention to the base of the brain, before commencing the study of the component parts which make up the two hemispheres.

The base of the brain presents for examination the under surfaces of the frontal and temporal lobes; the structures contained in the interpeduncular space, with the crura cerebri or cerebral peduncles; the under surfaces of the pons Varolii, cerebellum, and medulla oblongata; and the superficial origins of the cranial nerves.

The various objects exposed to view (with the exception of the origins of the cranial nerves, which will be considered in another section) in the middle line and on either side of the middle line, are here arranged in the order they are met with from before backward.

In the Middle Line.

Longitudinal fissure.
Rostrum and peduncles of
corpus callosum.
Lamina cinerea.
Optic commissure.
Tuber cinereum.
Infundibulum.
Pituitary body.
Corpora albicantia.
Posterior perforated space.
Pons Varolii.
Medulla oblongata.

On Each Side of the Middle Line.

Frontal lobe.
Olfactory lobe.
Fissure of Sylvius.
Optic tracts.
Crus cerebri.
Temporal lobe.
Hemisphere of cerebellum.

The **longitudinal fissure** partially separates the two hemispheres from each other. It divides completely the anterior portions of the two frontal lobes: and on raising the cerebellum and pons, it will be seen to separate completely the two occipital lobes: of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate part of the fissure is filled up by the great transverse band of white matter, the *corpus callosum*. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

The **corpus callosum** terminates at the base of the brain by a concave margin,

which is connected with the tuber cinereum through the intervention of a thin layer of gray substance, the *lamina cinerea*. This may be exposed by gently raising and drawing back the optic commissure. A white band may be observed on each side, passing backward from the under surface of the corpus callosum, across the posterior margin of the anterior perforated space to the hippocampal gyrus, where each meets the corresponding outer root of the olfactory tract: these bands are called the *peduncles of the corpus callosum*. They may be traced upward around the genu to become continuous with the *striae longitudinales* on its upper surface. Laterally, this portion of the corpus callosum extends into the frontal lobe.

The *lamina cinerea* is a thin layer of gray substance, extending backward from the termination of the corpus callosum above the optic commissure to the tuber cinereum; it is continuous on each side with the gray matter of the anterior perforated space, and forms the anterior part of the inferior boundary of the third ventricle.

The optic commissure is situated in the middle line, immediately in front of the tuber cinereum and below the *lamina cinerea*; that is to say, the commissure is superficial to the lamina in the order of dissection when the base is uppermost. It is the point of junction between the two optic tracts, and will be described with the cranial nerves. Immediately behind the diverging optic tracts, and between them and the peduncles of the cerebrum (*crura cerebri*), is a lozenge-shaped interval, the *interpeduncular space*, which is bounded behind by the pons Varolii, and in which are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The tuber cinereum is an eminence of gray matter, situated between the optic tracts, and extending from the corpora albicantia to the optic commissure, to which it is attached; it is connected with the surrounding parts of the cerebrum, forms part of the floor of the third ventricle, and is continuous with the gray substance in that cavity. From the middle of its under surface a conical tubular process of gray matter, about two lines in length, is continued downward and forward to be attached to the posterior lobe of the pituitary body. This is the *infundibulum*, and its canal, which is funnel-shaped, communicates with the third ventricle.

The pituitary body (*hypophysis cerebri*) is a small, reddish-gray, vascular mass, weighing from five to ten grains, and of an oval form, situated in the sella turcica, where it is retained by a process of dura mater, named the diaphragma sellæ. This process covers in the sella turcica, and has a small hole in its centre through which the infundibulum passes.

Structure.—The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior is the larger, of an oblong form, and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The *anterior lobe*, of a dark, reddish-brown color, is developed from the epiblast of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted tubules, lined by epithelium and united together by a very vascular connective tissue. The epithelium is columnar and occasionally ciliated. The alveoli sometimes contain a colloid material, similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatic and capillary blood-vessels. The *posterior lobe* is developed as an outgrowth from the embryonic brain, and during foetal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, and consists of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment. In the lower animals the two lobes are quite distinct, and it is only in the mammalia that they become fused together.

The corpora albicantia or *mammillaria* are two small, round, white masses, each about the size of a pea, placed side by side immediately behind the tuber

cinereum, and connected with each other across the mesial plane. They are mainly formed by the anterior crura of the fornix, which, after descending to the base of the brain, are twisted upon themselves to form loops, and constitute the white covering of the corpora albicantia. A second fasciculus, the *bundle of Vicq d'Azyr*, converges from the optic thalamus, and enters the anterior part of each body on its dorso-mesial surface. They are composed externally of white substance, and internally of gray matter; the nerve-cells of the gray matter are arranged in two sets, inner and outer, the cells of the former set being the smaller. They are also connected to the tegmentum by a small bundle of fibres, the peduncle of the mammillary body. At an early period of foetal life they are blended together into one large mass, but become separated about the seventh month. In most vertebrates there is only one median corpus albicans.

The **posterior perforated space** (*pons Tarini*) corresponds to a whitish-gray fossa placed between the corpora albicantia in front, the pons Varolii behind, and the crus cerebri on either side. It forms the posterior part of the floor of the third ventricle, and is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries.

FIG. 351.—Transverse vertical section of the brain, through the fore part of the foramen magnum, looked at from the front. (After Hirschfeld and Leveillé.)

The **pons Varolii** is situated immediately behind the two crura of the cerebrum. It consists of a broad band of white fibres, which pass transversely from one cerebellar hemisphere to the other; the band becoming narrower as it enters the cerebellum. In the middle line on its under surface a narrow groove runs from before backward and accommodates the basilar artery.

The **medulla oblongata** emerges from the posterior border of the pons Varolii; it is pyramidal in form, and is continuous below with the cervical portion of the spinal cord. It is marked on its ventral surface by a median fissure, continuous below with the anterior median fissure of the cord, and on either side by secondary fissures and columns, which will be described in the sequel.

The Frontal Lobe.—The under surface of the frontal lobe, sometimes named the orbital lobe, is seen on the anterior part of the base of the brain on either side of the median line. It has already been described (page 649).

The **fissure of Sylvius** at the base of the brain separates the frontal from the temporal lobe, and lodges the middle cerebral artery. It has also been described (page 645).

The **optic tracts** are well-marked flattened bands of fibres, which run obliquely across the crus cerebri on either side, and unite anteriorly to form the optic commissure. They will be described in connection with the cranial nerves.

The **crura cerebri** (*peduncles of the cerebrum*) are two thick cylindrical bundles of white matter, which appear in front of the anterior border of the pons, and diverge as they pass forward and outward to enter the under surface of each hemisphere. Each crus is about three-quarters of an inch in length, and is about the same in breadth anteriorly, but somewhat less posteriorly. They are marked upon their surface with longitudinal striæ, and each is crossed, just before entering the hemisphere, by the fourth nerve and the optic tract, the latter of which is adherent by its upper surface to the peduncle.

FIG. 352.—Section of the brain. Made on a level with the corpus callosum.

The Temporal Lobe.—The under surface of the temporal lobe is visible at the base of the brain, on either side of the crura and the structures contained in the interpeduncular space. It is separated anteriorly from the frontal lobe by the fissure of Sylvius, and behind is limited by the anterior border of the lateral hemispheres of the cerebellum. The fissures and lobes on its surface have already been described (page 652).

The **hemispheres of the cerebellum** are situated on either side of the middle line, and cover the occipital lobes of the cerebrum, when viewed from the base. The cerebellum differs much in appearance from the rest of the encephalon, being

of a darker color, while its convolutions are smaller and narrower, and arranged like the leaves of a book, and hence called *folia*.

General Arrangement of the Parts Composing the Cerebrum.—Each hemisphere, as already stated, consists of a central cavity, the *lateral ventricle*, surrounded by thick and convoluted walls of nervous tissue.

Interior of the Cerebrum.—If the upper part of either hemisphere is removed with a knife, about half an inch above the level of the corpus callosum, its internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of gray matter, which presents an equal thickness in nearly every part. This white central mass has been called the *centrum ovale minus*. Its surface is studded with numerous minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels. In inflammation or great congestion of the brain these are very numerous and of a dark color. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed, connecting them at the bottom of the longitudinal fissure; this is the *corpus callosum*. The margins of the hemispheres which overlap this portion of the brain are called the *labii cerebri*. Each labium is part of the callosal convolution already described; and the space between it and the upper surface of the corpus callosum is termed the *callosal fissure* (Fig. 348). The hemispheres should now be sliced off to a level with the upper surface of the corpus callosum, when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the *centrum ovale majus of Vieussens* (Fig. 352).

The Corpus Callosum.—The corpus callosum is a thick stratum of transversely directed nerve-fibres, by which probably almost every part of one hemisphere is connected with the corresponding part of the other hemisphere. The fibres of this body, when they pass from it into the hemispheres radiate in various directions, to terminate in the gray matter of the periphery. It thus connects the two hemispheres of the brain, forming their great transverse commissure, and at the same time roofs in the lateral ventricles. The best conception of its size and form is obtained by making an anterior posterior vertical section through the centre of the brain (Fig. 353). It is then seen to be a long, thick, irregularly flattened arch; in front taking a sharp bend, the *genu*, and dipping downward and backward to the base of the brain by a reflected portion, the *rostrum*, which is connected with the lamina cinerea; behind it terminates by a rounded end, which is folded over and is named the *splenium*. It is about four inches in length, and extends to within an inch and a half of the anterior, and two inches and a half of the posterior extremity of the cerebrum. It is somewhat broader behind than in front, and is thicker at either end than in its central part, being thickest behind. The reflected anterior portion of the corpus callosum is called the *beak* or *rostrum*; it becomes gradually thinner as it descends, and is attached by its lateral margins to the frontal lobes. At its termination, in addition to joining the lamina cinerea, the corpus callosum gives off two bands of white substance, the peduncles of the corpus callosum, already described (page 656).

Posteriorly, the corpus callosum forms a thick rounded fold, called the *splenium* or *pad*, which is free for a little distance as it curves forward, and is then continuous by its under surface with the fornix. The splenium overlaps the mesencephalon, but is separated from it by the pia mater, which is prolonged forward to form the velum interpositum. On its upper surface, the structure of the corpus callosum is very apparent, being collected into coarse transverse bundles. Along the middle line is a longitudinal depression, the so-called *raphé*, bounded laterally by two or more slightly elevated longitudinal bands, called the *striae longitudinales* or *nerves of Lancisi*; and, still more externally, other longitudinal striae are seen, beneath the callosal convolutions. These are the *striae longitudinales laterales*, or *tænia tectæ*. On each side of the middle line the under surface of the corpus cal-

losum forms the roof of the lateral ventricles, while in the mesial plane it is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms a vertical partition between the two ventricles. On each side the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere cannot pass directly across, but have to take a curved direction.

FIG. 353.—Vertical median section of the encephalon, showing the parts in the middle line.

1. Convolution of the corpus callosum. Above it is the calloso-marginal fissure.
2. Fissure of Rolando.
3. The parieto-occipital fissure.
- 4, 4, point to the calcarine fissure, which is just above the numbers. Between 2 and 3 are the convolutions of the quadrate lobe. Between 3 and 4 is the cuneate lobe.
5. The corpus callosum.
6. The septum lucidum.
7. The fornix.
8. Anterior crus of the fornix, descending to the base of the brain, and turning on itself to form the corpus albicans. The bundle of Vicq d'Azyr is indicated by a dotted line.
9. The optic thalamus. Behind the anterior crus

of the fornix a shaded part indicates the foramen of Monro; in front of the number an oval mark shows the position of the gray or middle commissure.

10. The velum interpositum.
11. The pineal gland.
12. The corpora quadrigemina.
13. The crus cerebri.
14. The valve of Vieussens (to the right of the number).
15. The pons Varolii.
16. The third nerve.
17. The pituitary body.
18. The optic nerve.
- 19 points to the anterior commissure, indicated by the oval outline behind the number.

The part of the corpus callosum which curves forward on each side from the genu into the frontal lobe and covers the front part of the anterior cornu of the lateral ventricle is called the *forceps anterior* or *minor*. The part which curves backward from each side of the splenium into the occipital lobe is known as the *forceps posterior* or *major*. Between these two parts on each side is the main body of the fibres, which extend laterally into the temporal lobe and cover in the body of the lateral ventricle. These are known as the *tapetum* or *mat*.

An incision should now be made through the corpus callosum, on either side of the raphé, when two large irregular cavities will be exposed, which extend through a great part of the length of each hemisphere. These are the lateral ventricles.

The Lateral Ventricles (Fig. 354).—The lateral ventricles, two in number, right and left, are irregular cavities situated in the lower and inner parts of the cerebral

hemisphere, one on either side of the middle line. They are separated from each other by a mesial vertical partition, the *septum lucidum*, but communicate with the third ventricle and indirectly with each other through the *foramen of Monro*. They are lined by a thin, diaphanous membrane, the *ependyma*, which is covered by ciliated epithelium, and are moistened by a serous fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a central cavity or *body*, and three prolongations from it, termed *cornua*. The *anterior* cornu curves forward and outward into the frontal lobe; the *posterior* backward and inward into the occipital lobe; and the *middle* descends into the *temporal* lobe.

The *central cavity* or *body* of the lateral ventricle is situated in the lower part of the parietal lobe. It is an irregularly curved cavity, triangular in shape on

FIG. 354.—The lateral ventricles of the brain.

transverse section, and presents a roof, a floor, and an inner wall. Its *roof* is formed by the under surface of the corpus callosum; its *inner wall* is the *septum lucidum*, which separates it from the opposite ventricle and connects the under surface of the corpus callosum with the *fornix*; its *floor* is formed by the following parts, enumerated in their order of position, from before backward: the *caudate nucleus* of the *corpus striatum*, *tænia semicircularis*, *optic thalamus*, *choroid plexus*, one-half of the *fornix* and its *posterior pillar*.

The *anterior cornu* passes forward and outward, with a slight inclination downward, from the *foramen of Monro* into the frontal lobe, curving round the anterior extremity of the *caudate nucleus*. It is bounded above by the corpus callosum, and below by the upper surface of its reflected portion, the *rostrum*. It is bounded internally by the anterior portion of the *septum lucidum*, and externally by the

head of the caudate nucleus of the corpus striatum. Its apex reaches the posterior surface of the genu of the corpus callosum.

The **posterior cornu** curves backward into the substance of the occipital lobe, its direction being backward and outward, and then inward; its concavity is therefore directed inward. Its roof is formed by the fibres of the corpus callosum passing to the temporal and occipital lobes. On its inner wall is seen a longitudinal eminence, which is in an involution of the ventricular wall produced by the calcarine sulcus; this is called the *hippocampus minor*, or *calcar avis*. Just above this the forceps major of the corpus callosum, sweeping round to enter the occipital lobe, causes another projection, which is known as the *bulb of the posterior horn*. The hippocampus minor and bulb of the posterior horn are extremely variable in their degree of development, being in some cases ill defined, while in others they are unusually prominent.

Between the middle and posterior cornu is a triangular area, called the *trigono-ventriculi* (see Descending Horn).

The **middle or descending cornu**, the largest of the three, traverses the temporal lobe of the brain, forming in its course a remarkable curve round the back of the optic thalamus. It passes at first backward, outward, and downward, and then curves round the crus cerebri, forward and inward, to within an inch of the apex of the temporal lobe, its direction being fairly well indicated on the surface of the brain by that of the parallel sulcus. Its upper boundary, or roof, is formed chiefly by the under surface of the tapetum of the corpus callosum, but the tail of the nucleus caudatus of the corpus striatum and the *tænia semicircularis* are also prolonged into it, and extend forward in the roof of the descending horn to its extremity, where they end in a mass of gray matter, the *amygdaloid nucleus*; this nucleus is merely a localized thickening of the adjacent gray cortex. Its lower boundary, or floor, presents for examination the following parts: the *hippocampus major*, *pes hippocampi*, *eminentia collateralis* or *pes accessorius*, *corpus fimbriatum*, prolonged from the posterior pillar of the fornix, and the *choroid plexus*. Along the mesial aspect of the descending cornu there is a cleft-like opening, which is the lower part of the *transverse fissure*, through which the choroid plexus of the pia mater is invaginated into the ventricle, but covered by the ependyma, which is pushed in before it.

The **corpus striatum** has received its name from the striped appearance which its section presents, in consequence of diverging white fibres being mixed with the gray matter which forms the greater part of its substance. The larger portion of this body is embedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the *extra-ventricular portion* or the *nucleus lenticularis*; a part, however, is visible in the ventricle and its anterior cornu: this is the *intra-ventricular portion*, or the *nucleus caudatus*.

The **nucleus caudatus** (Fig. 355) is a pear-shaped, highly arched mass of gray matter; its broad extremity is directed forward into the fore part of the body and anterior cornu of the lateral ventricle; its narrow end is directed outward and backward on the outer side of the optic thalamus; it is continued downward into the roof of the descending cornu, where it terminates in the *nucleus amygdalæ*, a collection of gray matter in the apex of the temporal lobe. It is covered by the lining of the ventricle, and crossed by some veins of considerable size. It is separated from the extra-ventricular portion, in the greater part of its extent, by a lamina of white matter, which is called the *internal capsule*, but the two portions of the corpus striatum are united in front.

The **nucleus lenticularis**, or extra-ventricular portion of the corpus striatum, is only seen in sections of the hemisphere. When divided horizontally, it presents, to some extent, the appearance of a biconvex lens, while a vertical transverse section of it gives a somewhat triangular outline. It does not extend as far forward or backward as the nucleus caudatus. It is bounded externally by a lamina of white matter called the *external capsule*, on the outer surface of which is a thin layer of gray matter termed the *claustrum*. The claustrum presents ridges and furrows on

its outer surface, corresponding to the convolutions and sulci of the island of Reil, from which it is separated by a thin white lamina.

Upon making a transverse vertical section through the middle of the nucleus lenticularis it is seen to present two white lines, parallel with its lateral border, which divide it up into three zones, of which the outer and largest is of a reddish color, and is known as the *putamen*, while the two inner are paler and of a yellowish tint, and are termed the *globus pallidus*. All three zones are marked by fine radiating white fibres, which are most distinct in the putamen. The gray matter of the corpus striatum is traversed by nerve-fibres, some of which are believed to originate in it. The cells are multipolar, both large and small; those of the lenticular nucleus containing yellow pigment.

FIG. 355.—Middle part of a horizontal section through the cerebrum at the level of the dotted line in the small figure of one hemisphere. (From Ellis, after Dalton.)

The **internal capsule** is formed by fibres of the crusta of the crus cerebri, supplemented by fibres derived from the corpus striatum and optic thalamus on each side. In horizontal section (Fig. 355) it is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the *genu*, and projects between the caudate nucleus and the optic thalamus. The portion in front of the genu is termed the *anterior limb*, and separates the lenticular from the caudate nucleus; the portion behind the genu is the *posterior limb*, and separates the lenticular nucleus from the optic thalamus. The internal capsule is composed largely of fibres, which, derived from the crusta of the crus cerebri, are continued through it to the cortex of the cerebral hemispheres, the fibres of the anterior limb passing to the frontal region; those from the genu and the anterior two-thirds of the posterior limb pass to the Rolandic area of the cortex, while those in the

hindermost third of the same limb pass to the temporo-occipital region. In addition to these, there are fibres which terminate in the corpus striatum and the optic thalamus; and other fibres derived from the gray matter of these two bodies, from the subthalamic region,¹ and from the hemisphere of the opposite side through the corpus callosum, which pass through the internal capsule to the cerebral cortex.

The **external capsule** is a lamina of white matter, situated on the outer side of the lenticular nucleus, between it and the claustrum, and is continuous with the internal capsule below and behind the lenticular nucleus. It is made up of fibres derived partly from the anterior white commissure and partly from the subthalamic region.

The **claustrum** is a thin layer of gray matter, situated on the outer surface of the external capsule. On transverse section it is seen to be triangular, with its apex directed upward and its base downward. Its inner surface, which is contiguous to the outer capsule, is smooth, but its outer surface presents ridges and furrows which correspond with the convolutions and sulci of the island of Reil, with which it is in close relationship. The claustrum is regarded as a detached portion of the gray matter of the island of Reil, from which it is separated by a layer of white fibres, the *capsula extrema* or *band of Baillarger*. Its cells are small and spindle-shaped, and contain yellow pigment; they are similar to those found in the deepest layer of the cortex.

The **tænia semicircularis** is a narrow, whitish band of medullary substance, situated in the depression between the caudate nucleus and the optic thalamus. Anteriorly its fibres are partly continued into the anterior pillar of the fornix; some, however, pass over the anterior commissure to the gray matter between the caudate nucleus and septum lucidum, while others penetrate the caudate nucleus. Posteriorly it is continued into the roof of the middle or descending horn of the lateral ventricle, at the extremity of which it enters the *nucleus amygdalæ*, an oval mass of gray matter, situated in the roof of the lower extremity of the descending horn. Like the corpus striatum, it is formed by a localized thickening of the gray matter of the cortex cerebri. Superficial to it is a large vein, *vena corporis striati*, which receives numerous small veins from the surface of the corpus striatum and optic thalamus; it runs forward and passes through the foramen of Monro to join the corresponding vena Galeni. On the surface of the vein of the corpus striatum is a narrow band of white fibres, named the *lamina cornea*.

The remains of the corpus callosum should now be removed in order to expose the fornix.

The **fornix** (Figs. 353, 354) is a longitudinal, arch-shaped lamella of white matter, situated beneath the corpus callosum, with which it is continuous behind, but separated in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for either hemisphere. The two portions are not united to each other in front and behind, but their central parts are joined together in the middle line. The two anterior, separated parts are called the *anterior pillars* (*columnæ fornicis*); the intermediate united portions constitute the *body of the fornix*; and the posterior parts, which are also separated from each other, are called the *posterior pillars* (*crura fornicis*).

The *body of the fornix* is triangular, narrow in front, broad behind. Its upper surface is connected, in the median line, to the septum lucidum in front, and the corpus callosum behind; laterally this surface forms part of the floor of each lateral ventricle. Its under surface rests upon the velum interpositum, which separates it from the third ventricle and the inner portion of the upper surface of the optic thalami. Its outer edge, on each side, is free, and is connected with the choroid plexuses.

The *anterior pillars* arch downward toward the base of the brain, separated

¹ The *subthalamic region* is the mass upon which the optic thalamus rests, and is an extension forward of the tegmentum of the mesencephalon (see page 674).

from each other by a narrow interval. They are composed of white fibres, which descend through the gray matter in the lateral wall of the third ventricle, and are placed immediately behind the anterior commissure. At the base of the brain, each pillar becomes twisted upon itself to form a loop, somewhat resembling the figure of 8. The lowest part of the loop constitutes the white matter of the corresponding *corpus albicans*, from which the fibres can apparently be traced upward and backward, as the *bundle of Vicq d'Azyr*, into the substance of the corresponding optic thalamus (Fig. 353). It must be stated, however, that there is probably no direct continuity between this bundle and the anterior pillar of the fornix—the latter possibly ending in the gray matter of the corpus albicans. The anterior crura of the fornix are joined in their course by the peduncles of the pineal gland and the superficial fibres of the *tænia semicircularis*, and receive fibres from the septum lucidum. Zuckerkandl describes an *olfactory fasciculus*, which becomes detached from the main portion of the anterior pillar of the fornix, and passes downward, in front of the anterior commissure, to the base of the brain, where it divides into two bundles, one joining the inner root of the olfactory tract; the other, the peduncle of the corpus callosum, and through it reaching the hippocampal convolution.

Between the anterior pillars of the fornix and the anterior extremity of the optic thalamus, an oval aperture is seen on each side; this is the foramen of Monro (Fig. 359). The two openings descend toward the middle line, and lead into the upper part of the third ventricle. Through this foramen the lateral ventricles communicate with the third ventricle, and consequently with each other; through it also the two choroid plexuses become joined with each other across the middle line. The boundaries of the opening are, above and in front, the anterior pillars of the fornix; behind, the anterior extremity of the optic thalamus.

The *posterior pillars* are the backward prolongations of the two halves of the body of the fornix. They are flattened bands, and, at their commencement, are intimately connected by their upper surfaces with the corpus callosum. Diverging from one another, each curves round the posterior extremity of the optic thalamus, and then passes downward and forward into the descending horn of the lateral ventricle. Here it lies along the concavity of the hippocampus major, on the surface of which some of its fibres are spread out, while the remainder are continued, as the *corpus fimbriatum* or *tænia hippocampi*, into the hook or uncus of the hippocampal convolution. Upon examining the under surface of the fornix, between its diverging posterior pillars, a triangular portion of the under surface of the corpus callosum may be seen. On it are a number of curved or oblique lines passing between the two pillars of the fornix. This portion has been termed the *lyra*, from the fancied resemblance it bears to a harp.

The *anterior commissure* is a bundle of white fibres, placed in front of the anterior pillars of the fornix, and appears to connect together the corpora striata. On transverse section it is seen to be oval in shape, its long diameter being vertical in direction and measuring about one-fifth of an inch. Its fibres can be traced backward and downward through the globus pallidus and below the putamen on each side into the substance of the temporal lobe. It serves in this way to connect the two temporal lobes, but it also contains fibres from the olfactory tract of the opposite side, the decussation of which in the anterior commissure may serve to explain the condition of crossed anosmia, *e. g.*, where there is a lesion in one temporal lobe with a loss of smell in the olfactory area of the opposite side of the nose.

The *septum lucidum* is a thin, double, vertically placed partition, which forms the internal boundary of the body and anterior horn of the lateral ventricle. It consists of two distinct laminæ, separated in part of their extent by a narrow chink or interval, called the *fifth ventricle*. It is a thin, semitransparent septum, attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix behind, and the reflected portion of the corpus callosum in front. It is triangular in form, broad in front and narrow behind; its inferior angle cor-

responds with the upper part of the anterior commissure. The outer surface of each lamina is directed toward the lateral ventricle, and is covered by the ependyma of that cavity, while its mesial surface bounds the cavity of the fifth ventricle.

Fifth Ventricle.—The fifth ventricle was originally a part of the great longitudinal fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum is therefore formed by the median wall of the hemisphere, and consists of an internal layer of gray matter, derived from the gray matter of the cortex, and an external layer of white substance continuous with the white matter of the cerebral hemispheres. The fifth ventricle differs from the other ventricles of the brain, inasmuch as it is not developed from the cavity of the cerebral vesicles, it is not lined by ciliated epithelium but by altered pia mater, and it does not communicate with the general ventricular cavity; further, the fluid it contains is of the nature of lymph.

The structures on the floor of the descending horn of the lateral ventricle will now be described.

The **hippocampus major**, or **cornu Ammonis** (Fig. 356), is a white eminence, about two inches in length, of a curved elongated form, extending throughout the

FIG. 356.—Transverse section of the middle horn of the lateral ventricle. (From a drawing by Mr. F. A. Barton.)

entire length of the floor of the descending horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presenting two or three rounded elevations with intervening depressions, it resembles the paw of an animal, and is called the *pes hippocampi*. If a transverse section is made through the hippocampus major, it will be seen that this eminence is produced by the folding of the cortex of the brain to form the dentate (hippocampal) sulcus. To the outer side and parallel with the hippocampus major an elongated eminence, the *eminentia collateralis*, is frequently recognized. It corresponds with the middle part of the collateral fissure, and its size depends on the direction and depth of this fissure. The main mass of the hippocampus major consists of gray matter, but on its ventricular surface is a thin layer of white matter, known as the *alveus*, which is continuous with the corpus fimbriatum of the fornix and is covered by the ependyma of the ventricle. Dr. J. G. Macarthy, of McGill University, Montreal, has shown¹ that, if the alveus and superficial strata of gray matter be reflected from the surface of the hippocampus by an incision carried along its convexity, the "core" of the hippocampus, as he terms it, presents in many cases a corrugated or crimped appearance.

¹ *Journal of Anat. and Phys.*, vol. xxiii., 1899.

The **corpus fimbriatum** or **fimbria** (*tænia hippocampi*) has already been mentioned as a part of the posterior pillar of the fornix. It consists of a narrow white band, which is placed immediately below the choroid plexus, and is attached by its deep surface to the white matter (alveus) of the hippocampus major as it courses through the descending cornu of the lateral ventricle. It can be traced as far as the uncus or hook of the hippocampal gyrus. Its inner margin is free, and rests upon the dentate convolution, from which it is separated by a slit-like fissure, the *fimbrio-dentate fissure*. Its outer margin is attenuated and irregular, and forms the line along which the ependyma is reflected over the choroid plexus as the latter is invaginated through the inferior part of the transverse fissure. When the choroid plexus is pulled away it carries the ependyma with it, and the descending horn opens on to the surface of the brain through the transverse fissure. If now the inner border of the corpus fimbriatum be raised, a notched band of gray matter, the gyrus dentatus, will be exposed; this has already been described as forming part of the limbic lobe (page 653).

FIG. 357.—Diagram showing the mode of formation of the velum interpositum.

The **choroid plexus** is a highly vascular, fringe-like structure, which is situated partly in the body and partly in the descending cornu of the lateral ventricle. It will be desirable to consider these two portions separately, in order to get a just conception of how they are formed.

The portion in the body of the ventricle is the vascular, fringed border of a triangular fold of pia mater, the *velum interpositum*, which lies on the under surface of the fornix and forms the roof of the third ventricle. It will be remembered that the developing brain vesicles are covered by pia mater. As the prolongation from the first vesicle, which is to form the cerebral hemispheres, increases in size, it grows backward and downward and covers the other vesicles, with the result that the pia mater covering the hemisphere comes in contact with that covering the upper surface of the second vesicle (Fig. 357).¹ A portion of the two layers which are in contact forms the velum interpositum. Immediately above is the body of the fornix, which is formed by the fusion of the cerebral hemispheres in the middle line and below is the cavity of the second vesicle (the third ventricle), with the optic thalamus on either side (Fig. 359). Just beyond the free lateral border of the fornix, between it and the *tænia semicircularis*, is a portion of the

¹ In the diagram the two layers are represented as being separated from each other, for the sake of clearness.

first cerebral vesicle, which is not developed into nervous matter but is made up only of ependyma covered by pia mater. The vessels of this portion of the highly vascular pia mater become dilated and prolonged, and grow into the ventricle, pushing the ependyma before them, and forming an irregular congeries of vessels, apparently encroaching on the cavity of the lateral ventricle, but in reality being external to it, because they are separated from it by the lining membrane of the cavity, the ependyma. This vascular structure is the choroid plexus of the body of the ventricle.

The part of the choroid plexus seen in the descending cornu is formed in exactly the same way, viz., by an ingrowth of the vessels of the pia mater into the cavity, pushing the ependyma before it, at a part of the wall of the horn where

FIG. 358.—The fornix, velum interpositum, and middle or descending cornu of the lateral ventricle.

there is a similar absence of nervous tissue and where it consists simply of pia mater and ependyma in close contact. This portion lies between the corpus fimbriatum in the floor and the tænia semicircularis in the roof of the descending horn. This area, destitute of nervous matter, is continuous with the area in the body of the ventricle, from which the choroid plexus of this region originated, and in it the vessels of its pia mater increase, and, invaginating the ependyma, appear in the descending horn as its choroid plexus. In the body of the ventricle the choroid plexus is really the vascular fringed margin of the velum; beyond the posterior margin of the velum the plexus of the descending horn is continuous with the pia mater on the surface of the gyrus hippocampi; the two portions of the plexus are, however, directly continuous with each other. The gap or cleft through which the invagination of the pia mater takes place is called the *transverse fissure*.

In front, the choroid plexus of the lateral ventricle is small and tapering, and communicates with that of the opposite side through the *foramen of Monro*. In structure it consists of minute and highly vascular villous processes, containing an afferent and efferent vessel, and covered by a single layer of flattened epithelium, the cells of which often contain a yellowish fat molecule. The anterior choroidal artery is derived from the internal carotid, and enters the ventricle at the extremity of the descending cornu, and, after ramifying in the plexus, sends branches into the adjacent parts of the brain. The posterior choroidal arteries, one or two in number, are derived from the posterior cerebral artery, and reach the plexus by passing forward under the splenium of the corpus callosum. The veins of the choroid plexus unite to form a prominent vein, which courses from behind forward to the foramen of Monro, and joins with the vein of the corpus striatum to form the corresponding vein of Galen.

The *transverse fissure* is not a real fissure or cleft, because it is filled by the invagination of the pia mater, forming the velum interpositum and the choroid plexuses, covered by the lining of the ventricular cavities. If this involution of pia mater is pulled out, the ventricular lining will necessarily be torn away with it, and a cleft-like space will be left on either side, extending from the foramen of Monro to the bottom of the descending horn of the lateral ventricle. The upper part of this cleft, that is to say, the part nearest the foramen of Monro, is between the lateral border of the body of the fornix and the optic thalamus; below this, at the commencement of the middle horn, it is between the commencing corpus fimbriatum of the fornix and the pulvinar of the optic thalamus; and lower still, in the descending horn, between the corpus fimbriatum on the floor and the tænia semicircularis in the roof of the cornu. Posteriorly the transverse fissure opens between the splenium of the corpus callosum above, and the corpora quadrigemina and pineal gland below. Through the fissure the *venæ Galeni* emerge to join the straight sinus.

The *velum interpositum* or *tela choroidea superior* (Fig. 358) is a vascular membrane, and is a prolongation of the pia mater into the interior of the brain through the middle part of the transverse fissure. It is of a triangular form, and separates the under surface of the body and posterior pillars of the fornix from the cavity of the third ventricle. Laterally it covers the inner part of the upper surface of the optic thalamus. Its posterior border or base lies beneath the splenium of the corpus callosum above, and the optic thalamus, the corpora quadrigemina, and pineal body below. Its anterior extremity, or apex, ends just behind the anterior pillars of the fornix, where it is connected with the anterior extremities of the choroid plexuses, which are here united through the foramen of Monro, and are then prolonged backward on the under surface of the velum as the *choroid plexuses of the third ventricle*; in front, these plexuses of the third ventricle lie close to the middle line, but diverge from each other behind. The lateral margins of the velum interpositum form the choroid plexuses of the lateral ventricles. It is supplied by the anterior and posterior choroidal arteries, already described. The veins of the velum interpositum, the *venæ Galeni*, two in number, run between its layers, each being formed by the union of the vein of the corpus striatum with the choroid vein. The *venæ Galeni* unite posteriorly into a single trunk, the *vena magna Galeni*, which terminates in the straight sinus (Fig. 326).

II. The Inter-brain.

The *inter-brain* (thalamencephalon) is the region of the third ventricle, and comprises the parts developed from the second cerebral vesicle, together with that portion of the first vesicle which is not concerned in the formation of the cerebral hemispheres.

The inter-brain is connected above and in front with the cerebral hemispheres; behind, with the mid-brain or mesencephalon. On its upper surface it is entirely concealed from view, as it is covered by those portions of the internal surfaces of

the cerebral hemispheres which have fused together to form the corpus callosum and the fornix, and is separated from the latter by the two layers of pia mater which form the velum interpositum. Inferiorly it reaches the base of the brain, forming the structures contained in the interpeduncular space.

The third ventricle is the cavity of the inter-brain (Fig. 359). It is a narrow median crevice between the two optic thalami, which constitute the side walls of the inter-brain. Its roof is formed by the velum interpositum, from which are suspended the choroid plexuses of the third ventricle. Its floor, somewhat oblique in its direction, is formed, from before backward, by the tuber cinereum, with its infundibulum and pituitary body; the corpora albicantia; the posterior perforated space; and the tegmenta of the crura cerebri. Its sides are formed by the optic thalami, and are limited above by a delicate band of white fibres, the *stria pinealis*,

FIG. 359.—The third and fourth ventricles. An arrow has been placed in the position of the foramen of Monro.

which runs along the junction of the mesial and upper surfaces of the optic thalamus to join the anterior pillars of the fornix. Its sides are somewhat convex, so that in the middle of the ventricle the two lateral walls are almost in contact, and are here united across the middle line by a band of gray nervous matter, the *middle, gray, or soft commissure*. The ventricle is bounded in front by the anterior pillars of the fornix and the lamina cinerea; behind by the pineal gland, the posterior commissure, and the upper end of the iter a tertio ad quartum ventriculum. The cavity is much deeper in front than behind, and presents a recess at its anterior part, which lies over the optic commissure and is therefore termed the *optic recess*. Behind and below this is the conical depression of the infundibulum, passing downward and forward to the pituitary body. At its posterior extremity the cavity

forms another and smaller recess, which extends into the stalk of the pineal gland, and is termed the *pineal recess*. At its upper and anterior part, immediately behind the anterior pillars of the fornix and in front of the optic thalamus, is an opening, the *foramen of Monro*, by which this ventricle communicates with the lateral ventricle on either side. The roof of the cavity is limited in front and behind by transverse bands of white matter, known respectively as the *anterior* and *posterior commissures*. The former has already been described in connection with the corpus striatum (page 665).

The *middle* or *soft commissure* consists almost entirely of gray matter. It connects the two optic thalami, and is continuous with the gray matter lining the anterior part of the third ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting; it is sometimes double.

The *posterior commissure* is a rounded band of white fibres, which stretches across from one optic thalamus to the other, overlying the upper end of the aqueduct of Sylvius, or iter a tertio ad quartum ventriculum. It is usually described as belonging to the inter-brain, but would appear to belong in part to the mid-brain, since some of its fibres are commissural and connect the anterior corpora quadrigemina to the fillet of the opposite side (see below). In addition there are other decussating fibres, which come from the tegmentum of the crus cerebri on one side and decussate with those of the opposite side in the posterior commissure, and passing through the optic thalamus reach the cerebral hemispheres. Fibres have also been described as taking their origin in the pineal body and ganglion habenulæ, and passing across to the posterior longitudinal bundle and oculomotor nucleus of the opposite side; these fibres occupy the ventral part of the commissure, and receive their myelin sheath before those in its dorsal part. But to a certain extent the posterior commissure belongs to the inter-brain, since it contains fibres which serve as commissural fibres between the two optic thalami.

The *optic thalami* are two large oblong masses, situated on either side of the third ventricle, and lying between the diverging portions of the corpora striata. They are composed mainly of gray matter, but their free surfaces are coated with a thin layer of white nervous tissue. They present outer and under surfaces, which are not free, but are blended with contiguous parts of the brain, and upper, inner, and posterior surfaces, which are free. The anterior extremity is narrow, and forms the posterior boundary of the foramen of Monro. The outer surface is in contact with the posterior limb of the internal capsule, which separates it from the lenticular nucleus. The *inferior* surface rests upon and is continuous with the tegmentum of the crus cerebri. Its upper surface is free, and is separated from the caudate nucleus by a furrow which lodges the lamina cornea, the vein of the corpus striatum, and the tania semicircularis. It is divided into an outer and an inner part by a groove which runs from behind, forward and inward. The outer part forms a portion of the floor of the lateral ventricle, and is covered by the ependyma of that cavity; it terminates in front in a tubercle, the *anterior tubercle* of the optic thalamus. The inner part is covered by the velum interpositum, which separates it from the fornix, and is excluded from both the lateral and third ventricles by the reflection of the lining of these cavities, and is therefore destitute of an ependymal covering.

The *internal* surface forms the lateral wall of the third ventricle, and running along its upper border is the peduncle of the pineal gland, from which the ependyma of the third ventricle is reflected on to the under surface of the velum interpositum. The *posterior* surface projects beyond the level of the corpora quadrigemina, and forms a well-marked rounded prominence, the *posterior tubercle* or *pulvinar*. The pulvinar is continued externally into a second eminence, the *external geniculate body*, which is placed above and to the outer side of the *internal geniculate body*, and from which it is separated by the superior brachium, one of the roots of the optic tract.

The optic thalamus is formed chiefly of gray matter, which is arranged in two masses, the *outer* and *inner nuclei*, and these are partially separated from each

other by an S-shaped vertical lamina of white matter, called the *internal medullary lamina*. This is named internal in contradistinction to a second or *external medullary lamina* of white matter, which coats the outer surface of the optic thalamus and connects it with the internal capsule. The inner nucleus is connected with the corresponding nucleus of the opposite side through the middle commissure of the third ventricle. The external nucleus, which is the larger of the two, extends backward into the pulvinar. The gray matter of the optic thalamus contains large multipolar and fusiform cells, and is traversed in every direction by numerous nerve-fibres.

The optic thalamus is intimately connected with the following structures :

1. It constitutes a relay for the greater number of the fibres of the tegmentum of the crus cerebri.

2. The pulvinar receives many of the fibres of the optic tract.

3. It is connected with the cerebral cortex, (a) through the *anterior stalk of the optic thalamus*, which passes from the anterior extremity of the thalamus through the anterior limb of the internal capsule to the frontal lobe; (b) through the *posterior stalk* or *optic radiations*, consisting of fibres which take their origin in the pulvinar and are transmitted through the extreme posterior part of the internal capsule to the occipital lobe; (c) through the *inferior stalk* or *ansa peduncularis*, made up of fibres which leave the inferior surface of the thalamus and end in the temporal lobe; (d) through fibres which pass from the external surface of the thalamus to the parietal lobe.

4. With the corpus striatum. The fibres destined for the caudate nucleus leave the external surface; those for the lenticular nucleus, the inferior aspect of the thalamus.

5. With the corpus albicans through the bundle of Vicq d'Azyr.

In connection with the optic thalamus two small nuclei of gray matter require consideration: (1) One of these, the *anterior nucleus*, is situated in the *anterior tubercle* of the optic thalamus. This nucleus receives the fibres (bundle of Vicq d'Azyr) which take origin in the cells of the corpus albicans (see page 657). Though this bundle of fibres appears to be the direct continuation of the anterior pillar of the fornix through the corpus albicans to the optic thalamus, it is believed to have no histological continuity with it. The fibres of the anterior pillar of the fornix form synapses in the corpus albicans around the cells which give origin to the bundle of Vicq d'Azyr, and thus an indirect communication only is established between the fornix and the optic thalamus. (2) The second gray nucleus lies in a depressed space, the *trigonum habenulæ*, situated between the pulvinar and the posterior part of the peduncle of the pineal gland. It is termed the *ganglion of the habenula*. It receives fibres from the peduncles of the pineal body, and sends off others which pass to a small collection of gray matter, situated between the diverging crura cerebri, and named the *ganglion interpedunculare*.

The pineal gland (*epiphysis cerebri*), so named from its peculiar shape (pinus, a *fir-cone*), is a small reddish gray body, conical in shape (hence its synonym, *conarium*), placed immediately above and behind the posterior commissure and between the anterior corpora quadrigemina, on which it rests. It is covered by the velum interpositum, which intervenes between it and the splenium of the corpus callosum. It is an upgrowth from the second cerebral vesicle (hence the name epiphysis), and is at first hollow, but soon becomes solid and loses its connection with the ventricular cavity. It is retained in its position by a duplicature of pia mater, derived from the under surface of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length and from two to three in width at its base, and is said to be larger in the child than in the adult, and in the female than in the male. It is attached on either side by a flattened stalk of white matter, the *pedunculus conarii*. This stalk consists of two laminae, upper and lower, separated by a little recess, the *pineal recess* (see page 671). The lower lamina is prolonged into the posterior commissure. The upper

divides into two strands, the *peduncles of the pineal gland*, or *striae pinealis*; these extend on either side along the optic thalamus at the junction of its mesial and upper surfaces (see page 671) to the anterior pillars of the fornix, with which they blend. The two stalks join together at their posterior extremity, in front of the pineal gland, forming a sort of festoon, and the base of the gland is connected to their posterior margin at the point of junction.

Structure.—The pineal gland consists of a number of follicles, lined by epithelium, and connected together by ingrowths of connective tissue. The follicles contain a transparent viscid fluid and a quantity of sabulous matter named *acervulus cerebri*, composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are present at all periods of life. They are found upon the surface of the pineal body and occasionally upon its peduncles.

Morphologically the pineal gland is regarded as the homologue of the structure termed the *pineal eye* of the lizards. In these reptiles the epiphysis cerebri is attached by an elongated stalk and projects through the parietal foramen. Its extremity lies immediately under the epidermis, and on microscopic examination presents, in a rudimentary fashion, structures similar to those found in the eyeball.

III. The Mid-Brain.

The mid-brain, or *mesencephalon*, is the constricted portion of the brain which connects the pons Varolii with the inter-brain and hemispheres, and hence it is frequently called the *isthmus cerebri*. It is developed from the third cerebral vesicle, the cavity of which becomes the aqueduct of Sylvius. It comprises the crura cerebri, the corpora quadrigemina, the geniculate bodies, and the Sylvian aqueduct. Its direction is from before backward and downward. In front and above it is continuous with the inter-brain; below with the pons. Its two surfaces are ventral and dorsal. They are free, but concealed: the ventral surface by the apices of the temporal lobes which overlap it; the dorsal, by the overhanging cerebral hemispheres. The ventral surface when exposed by drawing aside the temporal lobes, is seen to consist of two cylindrical bundles of white matter which emerge from the pons and diverge as they pass forward and outward to enter the inner and under part of either hemisphere. They are the *crura cerebri* or *cerebral peduncles*, and between them is a triangular area, already described as part of the interpeduncular space (see page 656); near the point of divergence of the crura the roots of the third nerve are seen to emerge in several bundles from a groove, the *sulcus oculomotorius*. The dorsal surface is not visible until a considerable portion of the cerebral hemispheres and other overlying structures have been removed. It then presents four rounded eminences placed in pairs, two in front and two behind, and separated from one another by a crucial depression. These are termed the *corpora* or *tubercula quadrigemina*. The ventral and dorsal surfaces meet on the side of the mid-brain, and are separated from each other by a furrow, the *lateral groove*, which runs from below upward and forward (Fig. 359).

If a cross section be made through the mesencephalon (Fig. 360) it will be seen that each lateral half is divided into two unequal portions by a lamina of deeply pigmented gray matter, named the *substantia nigra*; of these the postero-superior portion is named the *tegmentum*, and the antero-inferior the *crusta* or *pes*. The substantia nigra is curved on section with its concavity upward, and extends from the lateral groove externally to the oculomotor sulcus internally. The two crustæ are quite separate from one another, but the two halves of the tegmentum are joined

FIG. 360.—Transverse section of the mid-brain.

to each other in the mesial plane by a prolongation forward of the raphé or median septum of the pons. Laterally the tegmenta are free, but dorsally they blend with the corpora quadrigemina.

Crustæ.—The crustæ, which are two in number, separated by the interpeduncular space, are semilunar in section, and consist of longitudinal bundles of white fibres, which may be divided into three principal sets: (1) Those occupying the outer third of the crusta are believed to arise from the cells of the nuclei pontis, gray nuclei in the pons Varolii, and pass through the posterior part of the internal capsule to the cerebral cortex of the occipital and temporal lobes. (2) The fibres occupying the middle third of the crusta take their origin in the cells of the Rolandic area of the cortex, and, converging to the internal capsule, pass down through its genu and through the anterior two-thirds of its posterior limb to the crusta, from which they are prolonged through the pons into the anterior pyramid of the medulla oblongata. (3) The origin, from below, of the fibres occupying the inner third of the crusta is uncertain, though by some they are believed to arise in the crusta itself, from the cells of the locus niger. Above, they pass through the anterior part of the internal capsule to the cerebral cortex of the frontal lobe. In addition to these three sets of longitudinal fibres, a well-marked bundle, defined by having an oblique direction, must be noted. This is named the *mesial fillet*. It arises from the fillet (see below), and at the lower part of the crusta is situated at its mesial border; as it ascends it courses obliquely outward to reach the lateral border of the middle group of fibres (pyramidal tract) and becomes lost in the subthalamic region.

The **tegmentum**, or that portion of the mid-brain which is superior to the substantia nigra, consists of longitudinally directed strands of white fibres, which are separated from each other by transversely arched fibres. There is also a considerable quantity of gray matter. It thus forms a peculiar reticulated structure, which has been named *formatio reticularis*, and is similar to a like structure in the pons and medulla, with which it is continuous. In some parts of the tegmentum the longitudinal fibres are arranged in fairly well-defined tracts, which are as follows: 1. The *posterior longitudinal bundle*, which is composed of large nerve-fibres, and lies on either side of the median line, just below the aqueduct. These fibres are continued upward from the anterior column of the cord, in which they probably form short longitudinal commissures between its different segments. They pass through the pyramid of the medulla, then form the posterior longitudinal bundle of the pons, and enter the tegmentum; here they give off fibres to the nuclei of the third and fourth cranial nerves. At the front of the mid-brain some of the fibres of the posterior longitudinal bundle enter the posterior commissure and there decussate (see page 671); others pass upward to the subthalamic region. 2. Fibres from the superior cerebellar peduncle. These lie on either side of the middle line of the tegmentum, and, as they pass through it, decussate with each other, so that the fibres of one half of the cerebellum pass to the opposite half of the cerebrum. Having crossed to the opposite side, the bundle of fibres passes upward and forward, enclosing a mass of gray matter, the *red nucleus*, or *nucleus of the tegmentum*, from which it probably receives fibres, and eventually passes into the optic thalamus. 3. The *fillet*. This takes its chief origin in the medulla, and passes through the pons to the mid-brain, as will be described in the sequel. It forms a considerable bundle of longitudinal fibres in the ventral part of the tegmentum, and divides into three parts—the *upper*, *mesial*, and *lower fillet*. The *upper fillet* passes to the upper pair of corpora quadrigemina and the occipital region of the cerebral hemisphere. The *mesial fillet* has already been alluded to in the description of the crusta. After separating from the rest of the fillet its fibres assume an oblique direction, and are eventually lost in the subthalamic region. The *lower fillet*, also called *lemniscus*, is situated in the ventral part of the tegmentum, through which it passes obliquely and emerges at its side, and after crossing the superior peduncle of the cerebellum, passes to the inferior quadrigeminal bodies. It is reinforced by some fibres from the superior medullary velum. 4. Fibres from

the olivary nucleus, which pass in a longitudinal direction through the reticular formation of the tegmentum and are continued onward into the internal capsule.

The *red nucleus* or *nucleus of the tegmentum*, is a tract of gray matter situated on either side of the middle line, and is composed of numerous large cells, which are deeply pigmented. It is pierced by the fibres of the third nerve, and prolonged above into the posterior part of the subthalamie region.

The Substantia Nigra.—This, as already stated, is a layer of deeply pigmented gray matter, which separates the crista from the tegmentum. It is thicker internally than externally, where it is partially divided up by the mesial fillet passing from the tegmentum to the crista. It is traversed at its inner part by some of the fibres of origin of the third cranial nerve. The cells are small and multipolar, and are characterized by containing a large amount of dark pigment granules.

The *corpora* or *tubercula quadrigemina* are four rounded eminences placed in pairs, two in front and two behind, and separated from one another by a crucial depression. They are situated on the dorsal surface of the mid-brain, immediately behind the third ventricle and posterior commissure, and beneath the splenium of the corpus callosum. The *anterior* or *upper* pair, sometimes called the *nates*, are the larger. They are oval, their long diameter being directed forward and outward, and are of a gray color. The *posterior* or *lower* pair, called the *testes*, are hemispherical in form, and lighter in color than the preceding. From the outer side of each of these eminences, a prominent white band, termed *brachium*, is continued forward and outward. Those from the nates (*brachia anteriora*) pass obliquely outward between the pulvinar and the inner geniculate bodies into the external geniculate bodies. Those from the testes (*brachia posteriora*) lose themselves beneath an oval prominence on either side of the corpora quadrigemina, called the *internal geniculate body*. The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds they are hollow, and only two in number (*corpora bigemina*); they represent the anterior quadrigeminals of mammals. In these lower animals the corpora bigemina are frequently termed the *optic lobes*, because of their connection with the optic tracts. In the mammalia they are four in number, and solid. In the human foetus all four bodies are differentiated by the fifth month, and form at this time a considerable proportion of the brain.

The corpora quadrigemina are composed of white matter externally, and gray matter within. The *posterior* pair consist almost entirely of gray matter, covered over by a very thin stratum of white substance. Beneath the gray matter is a thin layer of white fibres, forming a part of the lower fillet. This separates the gray matter of the posterior corpora quadrigemina from the central gray matter of the aqueduct. The *anterior* pair are covered superficially by a thin stratum of white matter, the *stratum zonale*, the fibres of which are fine and arranged transversely. Beneath this is the *stratum cinereum*, a layer of gray matter which resembles a cup, semilunar in shape, thicker in the centre, and thinning off toward the margins, and consisting of numerous multipolar cells, for the most part of small size, embedded in a fine network of nerve-fibres. Below this again is the *stratum opticum*, or *upper gray-white layer*, characterized by the large amount of fine nerve-fibres which intersect the gray matter. These fibres vary in size in different parts of the layer, but have for the most part a longitudinal direction. The nerve-cells between the fibres are larger, and send their axis-cylinder processes into the next stratum. Finally there is the *stratum lemnisci*, or *deep gray-white layer*, which separates the rest of the body from the gray matter around the aqueduct. It consists of fibres partly derived from the upper fillet and partly from the cells of the preceding layer. Interspersed among these fibres are nerve-cells of large size.

In close relationship with the corpora quadrigemina are the *superior peduncles of the cerebellum*. They emerge from the upper and mesial part of the hemispheres of the cerebellum, and run upward and forward to the corpora quadri-

gemina, with which they come in close contact. They then pass under these bodies, through the tegmentum (*vide supra*), and enter the optic thalamus.

The **corpora geniculata** are two small, oblong masses on each side, situated behind and beneath the posterior end of the optic thalamus, and named, from their position, *corpus geniculatum externum* and *internum*. These two bodies are separated from each other by the brachium anterius of the anterior quadrigeminal body. It is convenient and customary to describe these two bodies together, but the student should bear in mind that the corpus geniculatum externum belongs in reality to the optic thalamus; the corpus geniculatum internum alone being a part of the mid-brain. The *external* geniculate body is of a dark color, and presents a laminated arrangement, consisting of alternate layers of gray and white matter. Its cells are large, multipolar, and pigmented; their processes are intimately related with the visual area in the cerebral cortex of the occipital region. It is believed that the intercellular gray matter of these bodies is composed, to a considerable extent, of the terminations of the optic nerve, which form synapses around the cells. The *internal* geniculate body is smaller in size, lighter in color, and does not present a laminated arrangement. It receives the posterior brachium from the inferior quadrigeminal body, and some of the fibres of the optic tract appear to enter it. The internal geniculate bodies are connected with each other through the optic commissure by a band of fibres named *Gudden's commissure* (see page 721). The anterior quadrigeminal body, the pulvinar, and the external geniculate body are intimately concerned with vision. They constitute the lower cerebral centre for the optic nerve-fibres which end in them. Extirpation of the eyes in newly born animals entails an arrest of their development, but has no effect on the posterior quadrigeminal body or the internal geniculate body. These latter also are well developed in the mole, where the superior quadrigeminal body is rudimentary.

The Aqueduct of Sylvius, or Iter a Tertio ad Quartum Ventriculum.—This is a narrow canal, about half an inch in length, situated between the corpora quadrigemina and the tegmentum, and connecting the third with the fourth ventricle. Its shape on transverse section varies, being T-shaped below, triangular above, and oval about the middle of its course. It is lined by columnar ciliated epithelium, and surrounded by a layer of gray matter, called the *central gray matter of the aqueduct*, which is continuous with the gray matter of the third and fourth ventricles. This gray matter is separated above from that of the corpora quadrigemina by the stratum lemnisci; below it, is the posterior longitudinal bundle and the formatio reticularis of the tegmentum. The central gray matter is more abundant below the canal than above it. Here are certain defined group of cells, which are connected with the roots of the third, fourth, and fifth cranial nerves.

Subthalamie Region.—One other structure, to which allusion has already been made, requires mention in this connection; it is the *subthalamie region*. It is a prolongation forward of the tegmentum of the crus cerebri, which becomes continuous with the lower surface of the optic thalamus. Toward the anterior part of the crus cerebri the tegmentum becomes thinned out, and is blended with the superjacent portion of the optic thalamus. To this region, the name *subthalamie tegmental region* has been given. In front it is lost at the base of the brain in the gray matter of the anterior perforated space, and is continuous with the gray matter of the floor of the third ventricle. The subthalamie tegmental region contains a forward prolongation of the red nucleus, and consists from above downward of three layers: (1) *stratum dorsale*, which is directly applied to the under surface of the optic thalamus, and consists of fine longitudinal fibres; (2) *zona incerta*, a continuation forward of the formatio reticularis of the tegmentum; and (3) the *corpus subthalamieum*, a mass of gray matter which on section presents a lenticular shape, and lies immediately above the substantia nigra.

STRUCTURE OF THE CEREBRUM.

The **cerebrum**, like the other parts of the great nerve centre, is composed of gray and white matter. In order to give some general idea of its construction, at all events in part, it may be compared, for the sake of illustration, to a tree, the trunk of which divides into two main divisions, and these break up into smaller branches, which finally end in twigs, to which are attached the leaves, forming an investment to the branches and covering the whole tree. The trunk is represented by the medulla oblongata as it passes through the foramen magnum; the two main divisions by the *crura cerebri*, which break up into smaller branches; these diverge from each other, dividing and subdividing, until they reach the surface of the hemispheres, where they terminate in single nerve-fibres, which are continuous with the basal axial cylinder processes of the nerve-cells, the representatives of the leaves. These cells are arranged on the surface, resembling a cap, covering the hemispheres, and constitute the cerebral cortex. But here the analogy ends, for in the cerebrum there are, in addition to this cortex, other masses of gray matter situated in the middle of the brain; and other white fibres besides the diverging ones that have been mentioned, and which serve either to connect the two cerebral hemispheres, or to unite different structures in the same hemisphere.

The **white matter of the cerebrum** consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course they take. 1. Projection or peduncular fibres, which connect the hemisphere with the medulla oblongata and cord. 2. Transverse or commissural fibres, which unite together the two hemispheres. 3. Association fibres, which connect different structures in the same hemisphere. These are, in many instances, collateral branches of the projection fibres, but others are the axons of independent cells.

1. The **projection or peduncular fibres** consist of fibres which pass either to or from the cord. They form the longitudinal fibres of the pons, and at its upper border divide into two main groups, which, diverging from each other, constitute the *crura cerebri* or *cerebral peduncles*. In the *crura cerebri*, as has been before described, the diverging fibres are arranged in two strata, which are separated by the substantia nigra; the ventral or superficial stratum forming the *crusta* of these bodies, and the dorsal or deeper stratum, the *tegmentum*. The fibres derived from these two sources take a different course, and will have to be separately considered.

The fibres of the *crusta* are derived from the pyramid of the medulla, and are continued upward through the pons; they are reinforced in their passage through the crus by accessory fibres, derived from the central gray nucleus around the Sylvian aqueduct and from the substantia nigra. When they emerge from the crus, most of the fibres pass through the internal capsule, and when they leave it, spread out forward, upward, and backward, forming a series of radiating fibres, the *corona radiata*, which proceed to the cortex. As the fibres pass through the internal capsule they give off branches to the optic thalamus and to the caudate and lenticular nuclei of the striate body, and other fibres, derived especially from the first of these ganglia, form a part of the corona radiata, and pass to the cortex of the cerebral hemispheres. The fibres of the *tegmentum* are continuous with those longitudinal fibres of the pons which are derived from the nucleus gracilis and nucleus cuneatus, and from the formatio reticularis of the medulla. They are reinforced by fibres from the corpora quadrigemina and the corpora geniculata, and from the superior peduncle of the cerebellum. Some of the fibres are continued directly to the cerebral cortex, but the majority pass to the subthalamic region, and either end there or in the substance of the optic thalamus—the connection with the cortex being effected by means of fibres which arise in the optic thalamus. They spread out to form part of the corona radiata, and are distributed especially to the cortex of the temporal and occipital lobes.

2. The **transverse or commissural fibres** connect the two hemispheres. They

include: (a) the transverse fibres of the corpus callosum; (b) the anterior commissure; (c) the posterior commissure, and have already been described.

3. **Association Fibres.**—These connect different structures in the same hemisphere, and are of two kinds: (1) Those which unite adjacent convolutions, *short association fibres*; (2) those which pass between more distant parts in the same hemisphere, *long association fibres*.

The *short association fibres* are situated immediately beneath the gray substance of the cortex of the hemispheres, and connect together adjacent convolutions.

The *long association fibres* include the following: (a) the uncinate fasciculus; (b) the cingulum; (c) the superior longitudinal fasciculus; (d) the inferior longitudinal fasciculus; (e) the perpendicular fasciculus; and (f) the fornix.

(a) The *uncinate fasciculus* passes across the bottom of the Sylvian fissure, and connects the convolutions of the frontal lobe with the anterior end of the temporal lobe.

(b) The *cingulum* is a band of white matter which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forward and upward parallel with the rostrum, winds round the genu, runs in the convolution from before backward, immediately above the corpus callosum, turns round its posterior extremity, and passes into the hippocampus major, through which it courses to its anterior extremity.

(c) The *superior longitudinal fasciculus* runs along the convex surface of the hemisphere, and connects the frontal and occipital and the frontal and temporal lobes.

(d) The *inferior longitudinal fasciculus* is a collection of fibres which connects the temporal and occipital lobes, running along the outer wall of the descending and posterior cornua of the lateral ventricle.

(e) The *perpendicular fasciculus* runs vertically through the front part of the occipital lobe, and connects the inferior parietal lobule with the fourth temporal convolution.

(f) The *fornix* connects the hippocampal convolution with the corpus albicans, and, by means of the bundle of Vicq d'Azyr, with the optic thalamus (see page 672). Through the fibres of the lyra it probably also unites the opposite hippocampal convolutions.

The **gray matter of the cerebrum** is disposed in two great groups: (1) The gray matter of the cerebral cortex. (2) The gray matter of the basal ganglia, the nucleus caudatus and the nucleus lenticularis of the corpus striatum; the claustrum and the amygdaloid nucleus. They are, with the exception of the amygdaloid nucleus, situated to the inner side of the island of Reil, and form with this convolution the oldest part of the hemisphere, for they are the first parts of the encephalon to be differentiated in the development of the individual. They are simply semi-detached local thickenings of the gray cortex. The optic thalamus is not reckoned as a basal ganglion, but as belonging to the thalamencephalon.

GRAY MATTER OF THE CORTEX.

On examining a section through one of the convolutions of the Rolandic area with a lens, it is seen to consist of alternating white and gray layers thus disposed from the surface inward: (1) a thin layer of white substance; (2) a layer of gray substance; (3) a second layer of white substance (outer band of Baillarger or band of Gennari); (4) a second gray layer; (5) a third white layer (inner band of Baillarger); (6) a third gray layer, which rests on the medullary substance of the convolution.

The cortex is made up of nerve-cells which vary in size and shape, and of nerve-fibres, which are either medullated or naked axis-cylinders, embedded in a matrix of neuroglia.

Nerve-cells.—According to Cajal, whose description is now generally accepted, the nerve-cells are arranged in four layers, named from the surface inward as follows: (1) the molecular layer; (2) the layer of small pyramidal cells; (3) the layer of large pyramidal cells; (4) the layer of polymorphous cells.

The Molecular Layer.—In this layer the cells are polygonal, triangular, or fusiform in shape. Each polygonal cell gives off some four or five dendrites, while its axon may arise directly from the cell or from one of its dendrites. The axons and dendrites of these cells ramify in the molecular layer. Each triangular cell gives off two or three dendrites, from one of which the axon arises, the dendrites and the axon ramifying in the molecular layer. The fusiform cells are placed with their long axes parallel to the surface and are mostly bipolar, each pole being prolonged into a dendrite, which runs horizontally for some distance and furnishes ascending branches. Their axons, two or three in number, arise from the dendrites, and, like them, take a horizontal course, giving off numerous ascending collaterals. The distribution of the axons and dendrites of all three sets of cells is limited to the molecular layer.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in these two layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axis-cylinder, and this passes into the central white substance, giving off collaterals in its course, and is distributed as a projection, commissural, or association fibre. Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen, when prepared by the silver or methylene-blue method, to be studied with projecting bristle-like processes. The larger pyramidal cells, especially in the Rolandic area, may exceed $50\ \mu$ in length and $40\ \mu$ in breadth, and are termed *giant cells*.

Layer of Polymorphous Cells.—The cells in this layer, as their name implies, are very irregular in contour, the commonest varieties being of a spindle, star, oval, or triangular shape. Their dendrites are directed outward, toward, but do not reach, the molecular layer; their axons pass into the subjacent white matter.

There are two other kinds of cells in the cerebral cortex, but their axons pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (a) the cells of Golgi, the axons of which do not become medullated, but divide immediately after their origin into a large number

FIG. 361.—The four layers of cells in the cerebral cortex. (After Cajal.) Modified from Testut.

of branches, which are directed toward the surface of the cortex; (*b*) the cells of Martinotti, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axons pass out into the molecular layer and form an extensive horizontal arborization.

Nerve-fibres.—These fill up a large part of the intervals between the cells, and may be medullated or non-medullated—the latter comprising the axons of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse (tangential or horizontal) or vertical (radial). The *transverse fibres* run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They consist of several strata, of which the following are the most important: (1) a stratum of white fibres covering the superficial aspect of the molecular layer; (2) the external band of Baillarger, or band of Gennari, which runs through the layer of large pyramidal cells; (3) the internal band of Baillarger, which intervenes between the layer of large pyramidal cells and the polymorphous layer. According to Cajal, the transverse fibres consist of (*a*) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (*b*) the arborizations of the axons of Golgi's cells; (*c*) the collaterals and terminal arborizations of the projection, commissural, or association fibres. The *vertical fibres*.—Some of these, viz., the axons of the pyramidal and polymorphous cells, are directed toward the central white matter, while others, the terminations of the commissural, projection, or association fibres, pass outward to end in the cortex. The axons of the cells of Martinotti are also ascending fibres.

In certain parts of the cortex this typical structure is departed from. The chief of these regions are: (1) the occipital lobe, (2) the hippocampus major, (3) the dentate convolution, and (4) the olfactory bulb.

Special Types of Gray Matter.

1. In the cuneus and the calcarine fissure of the occipital lobe, Cajal has recently described as many as nine layers. Here the inner band of Baillarger is absent; the outer band of Baillarger (band of Gennari) is, on the other hand, of considerable thickness. If a section be examined microscopically, an additional layer is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axon arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like cells with ascending axons (cells of Martinotti). This area of the cortex forms the visual centre, and it has been shown by Dr. J. S. Bolton¹ that in old standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

2. In the hippocampus major the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (*a*) *S. convolutum* or *S. granulosum*, containing many tangential fibres; (*b*) *S. lacunosum*, presenting numerous lymphatic or vascular spaces; (*c*) *S. radiatum*, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and the cells are mostly of large size. The axons of the cells in the polymorphous layer may run in an ascending, descending, or horizontal direction. Between the polymorphous layer and the ventricular endyma is the white substance of the alveus.

3. In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

4. **The Olfactory Bulb.**—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the cavity of the

¹ *Phil. Trans. of Royal Society, Series B, vol. cxliii, p. 165.*

lateral ventricle. In man the original cavity is filled up by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white matter, but it is scanty and ill defined. A section through the ventral part shows it to consist of the following layers from without inward. (1) A layer of olfactory nerve-fibres, which are the non-medullated axons prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrons of the mitral cells, presently to be described. (2) *Glomerular layer*.—This contains numerous spheroidal reticulated enlargements, termed *glomeruli*, which are produced by the branching and arborization of the processes of the olfactory nerve-fibres with the descending dendrite of the mitral cells. (3) *Molecular layer*.—This is formed of a matrix of neuroglia, embedded in which are the *mitral cells*. These cells are pyramidal in shape, and the basal part of each gives off a thick dendron which descends into the glomerular layer, where it arborizes as indicated above, and others which interlace with similar dendrites of neighboring mitral cells. The axons pass through the next layer into the white matter of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) *Nerve-fibre layer*.—This lies next the central core of neuroglia, and its fibres consist of the axons or afferent processes of the mitral cells which are passing to the brain; some efferent fibres are, however, also present, and terminate in the molecular layer, but nothing is known as to their exact origin.

IV. The Hind-Brain.

The *hind-brain*, or *epencephalon*, comprises those parts which are developed from the fourth cerebral vesicle; namely, the pons, the cerebellum, and the upper half of the fourth ventricle.

PONS VAROLII.

The *pons Varolii* (*tuber annulare*) is the bond of union of the various segments of the encephalon, connecting the cerebrum above, the medulla oblongata below, and the cerebellum behind. It is situated above the medulla oblongata, below the crura cerebri, and between the hemispheres of the cerebellum. It is about an inch in length and in thickness, and about an inch and a half in width. It presents four surfaces: *superior*, which is attached, by direct continuation of fibres, to the mid-brain; *inferior*, which is continuous with the medulla oblongata; while the *anterior* or *ventral* and the *posterior* or *dorsal* surfaces are free.

The *anterior* or *ventral* surface is very prominent, markedly convex from side to side, and less so from before backward. It consists of transverse white fibres, which arch like a bridge across the middle line, and on either side are gathered together into a compact mass, forming the *middle peduncle of the cerebellum*. Above and below it presents a well-defined border; below, its transverse fibres slightly overlap the pyramidal bodies of the medulla, which disappear into its substance; above, the transverse fibres slightly overlap the crura cerebri which emerge from it. This surface rests upon the clivus of the sphenoid bone, and presents in the middle line a longitudinal groove, wider in front than behind, in which rests the basilar artery.

The *posterior* or *dorsal* surface of the pons is free, but is concealed from view by the cerebellum. It forms the upper part of the floor of the fourth ventricle, and will be described with this cavity.

Structure.—Transverse sections of the pons Varolii show that it consists of two parts, which differ in appearance and structure from each other: the anterior or *ventral* portion consists for the most part of fibres arranged in transverse and longitudinal bundles with a small amount of gray matter; the posterior or *dorsal* portion is a continuation of the reticular formation of the medulla, and is called

the *tegmental* portion, as most of its constituents are continued into the tegmentum of the crus cerebri.

The anterior or ventral part consists of three layers of fibres: 1. superficial transverse fibres; 2. longitudinal fibres; 3. deep transverse fibres. These three layers are not, however, completely differentiated from each other, for some transverse fibres may be seen between the bundles of the longitudinal fibres (Fig. 362).

1. The *superficial transverse fibres*, consisting of a rather thick layer on the ventral surface of the pons, cross the middle line, and proceeding laterally are collected into a large rounded bundle of fibres on each side. This bundle, with the addition of some transverse fibres from the deeper part of the pons, forms the *middle peduncle* of the cerebellum of the corresponding side.

2. The *longitudinal fibres* enter the pons below as a single mass, which forms the continuation upward of the fibres of the pyramids of the medulla; as they ascend they become broken up into bundles by some of the transverse fibres, and

FIG. 362.—Superficial dissection of the medulla oblongata and pons. (Ellis.)

are continued into the crura of the mid-brain. They lie on either side of the middle line, and cause a bulging of the superficial transverse fibres on the ventral surface of the pons, with a longitudinal mesial groove between them. This is the groove, mentioned above, in which the basilar artery is received. As the fibres ascend they are increased in number, being reinforced by others derived from the nerve-cells in the deep transverse strata.

3. The *deep transverse fibres* form a thicker layer than the superficial set, and there is much gray matter between them. The fibres pass from the middle line, where they interlace with those from the opposite side, and, coursing to the lateral borders of the pons, they, for the most part, curve dorsally, and assist the superficial transverse fibres in forming the middle peduncle of the cerebellum. Some of the fibres join the nerve-cells which are situated in the gray matter of this layer, and in addition nerve-fibres derived from others of these cells pass off to join the longitudinal fibres (see above).

The *tegmental* or *dorsal portion* of the pons is chiefly constituted by a continuation upward of the reticular formation and gray matter of the medulla. It is subdivided into lateral halves by a median raphe continuous with that of the medulla, but this does not extend into the ventral half of the pons, being here obliterated by the transverse fibres.

The dorsal portion of the pons, like the ventral, contains both transverse and longitudinal fibres. The transverse fibres are collected into a distinct bundle, which, from its shape, is sometimes termed the *trapezium* or *corpus trapezoides*. It consists of fibres which proceed laterally to become connected with the cells of the accessory auditory nucleus. The longitudinal fibres, which are continuous with those of the medulla, are mostly collected into two bundles on either side. One of these lies between the corpus trapezoides and the formatio reticularis of the pons, and is a continuation upward of the sensory tracts; it is termed the *fillet*. The other bundle is situated more dorsally, near the floor of the fourth ventricle; it is the *posterior longitudinal bundle*, and contains both ascending and descending fibres. Other longitudinal fibres, which are more diffusely distributed, arise from the cells of the gray matter of the pons itself. The greater part of the dorsal portion of the pons is, as stated above, a continuation upward of the formatio reticularis of the medulla, and, like it, presents, on transverse section, viewed under a moderate magnifying power, a reticular appearance. In addition to the gray matter, which presents a number of small reticularly arranged masses, with nerve-cells, there are some important collections of nerve-cells which require mention.

1. The **superior olivary nucleus** is a small isolated collection of gray matter, situated on the dorsal surface of the outer part of the trapezium. In structure it resembles the inferior olivary nucleus of the medulla, presently to be described, and is situated immediately above it. The nerve-fibres derived from its cells pass into the trapezium, and, as stated above, cross the middle line and enter the accessory auditory nucleus of the other side. The other collections of nerve-cells in the formatio reticularis of the pons are nuclei from which some of the cranial nerves arise.

2. **Nuclei of the Fifth Nerve.**—The nuclei of the fifth nerve in the pons are two in number: one for the motor root and the other for the sensory. The *motor* nucleus is situated in the higher portion of the pons, close under the dorsal surface and along the line of the lateral margin of the fourth ventricle. The *sensory* nucleus lies external to the motor one, beneath the superior peduncle of the cerebellum, which forms the lateral boundary of the upper half of the fourth ventricle. Some of the fibres from these nuclei pass to the raphe of the pons, and thence probably to the higher parts of the brain; the rest form the nerve-roots of the motor and sensory parts of the fifth nerve respectively. They pass through the pons to emerge on its ventral surface at its lateral and constricted portion, nearer its superior than its inferior margin. It must be mentioned that the whole of the roots of the fifth nerve are not formed from these nuclei. The sensory root is partly formed by a long tract of fibres, known as the *ascending* root, which can be traced through the pons and medulla to the upper part of the spinal cord. The motor root, in like manner, is partly formed by a long tract of fibres, which passes downward from the gray matter in the floor of the Sylvian aqueduct and which is termed the *descending* root.

3. The **nucleus of the sixth nerve** is situated beneath the floor of the fourth ventricle, on either side of the middle line. It lies close to the root of the facial nerve, immediately to be described, being a little external to and beneath it, and corresponds to the upper half of the fasciculus teres of the floor of the fourth ventricle (Fig. 371). The fibres pass through the substance of the pons, and emerge at the lower margin of this structure, between it and the upper end of the medulla.

4. The **nucleus of the facial nerve** is of elongated form, and is situated deeply in the reticular formation below the floor of the fourth ventricle and dorsal to

the superior olivary nucleus. The roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backward and inward till they reach the floor of the fourth ventricle, close to the median groove, where they are collected into a rounded bundle. This passes upward and forward, producing an elevation (*fasciculus teres*) in the floor of the ventricle, and then takes a sharp bend and arches outward through the substance of the pons to emerge at its lower border in the interval between the olivary and restiform bodies of the medulla.

5. The **nuclei of the auditory nerve** are two in number, dorsal and ventral. The *dorsal* nucleus is principally situated in the medulla, but is prolonged upward into the pons, where it lies beneath the upper half of the floor of the fourth ventricle. The *ventral* or accessory nucleus is also partly contained in the medulla and partly in the pons. In the medulla it is situated on the antero-external surface of the restiform body, lying between the vestibular and cochlear divisions of the auditory nerve, the latter being to its outer side. In the pons it is seen to lie beyond the boundary of the fourth ventricle on the outer and ventral aspect of the restiform body. A third nucleus (*nucleus of Deiters*) is sometimes termed the outer nucleus of the auditory nerve. It is situated below the outer angle of the fourth ventricle, and contains multipolar nerve-cells of large size. The root of the auditory nerve consists of two portions, lateral and mesial, which pass, one to the outer and the other to the inner side of the restiform body, those from the lateral part arising mainly from the ventral nucleus, those from the mesial part arising from the dorsal auditory nucleus. They emerge at the lower border of the pons, in the groove between the olivary and restiform bodies.

The Nuclei Pontis.—In addition to these nuclei of gray matter, which have been described as being situated in the tegmental or dorsal portion of the pons, there are small masses of gray matter, as mentioned above, in the anterior or ventral portion. These are known as the *nuclei pontis*, and consist of small multipolar nerve-cells, scattered between the bundles of transverse fibres.

THE CEREBELLUM.

The **Cerebellum** is contained in the inferior occipital fossæ, and is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium cerebelli. In form, it is oblong and flattened from above downward, its great diameter being from side to side. It measures from three and a half to four inches transversely, two to two and a half inches from before backward, and is about two inches thick in the centre, and about six lines at the circumference. It consists of gray and white matter: the former, darker than that of the cerebrum, occupies the surface; the latter, the interior. The surface of the cerebellum is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminæ of which it is composed.

Lobes of the Cerebellum.—The cerebellum consists of three parts or lobes, a median and two lateral. They are all continuous with each other, and are substantially the same in structure. The median portion is called the *worm* or *vermiform process*, from the annulated appearance which it presents, owing to transverse ridges and furrows upon it. On the upper surface of the cerebellum, the worm is only slightly elevated above the level of the lateral portions, but on the under surface it is sunk almost out of sight in a deep depression, which is called the *vallecula*. The lateral parts are called *hemispheres*; they attain a considerable size, overlapping and obscuring the inferior part of the worm. Below and behind they are separated by a deep notch (*posterior cerebellar notch, incisura marsupialis*), and in front by a broader, shallower notch (*anterior cerebellar notch, incisura semilunaris*). The *anterior* notch lies close to the pons and upper part of the medulla, and its upper edge encircles the posterior corpora quadrigemina. The *posterior* notch is free, and contains, in the recent state, the upper part of the falx cerebelli.

The sides of the notches are formed by the margins of the hemispheres, while the bottom of the notches is formed by the anterior and posterior extremities of the worm respectively. The cerebellum is characterized by its laminated or foliated appearance; it is everywhere marked by deep, transverse, somewhat curved fissures, which lie close together, and extend for a considerable depth into the substance of the cerebellum, dividing it into a series of layers or leaves. Upon making sections across the laminae it will be seen that the folia, though differing in appearance from the convolutions of the cerebrum, are homologous with them, inasmuch as they consist of a central white substance, with a covering or cortex of gray matter.

The largest and deepest fissure is the *great horizontal fissure*. It commences in front at the pons, and passes horizontally round the free margin of the hemisphere to the middle line behind, and divides the cerebellum into an upper and

FIG. 363.—Upper surface of the cerebellum. (Schäfer.)

lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual folia or laminae from each other.

The cerebellum is connected to the cerebrum, pons, and medulla by three pairs of peduncles; which will be described in the sequel; a *superior* pair, connect it with the cerebrum; a *middle* pair, with the pons; and an *inferior* pair, with the medulla.

Upper Surface of Cerebellum (Fig. 363).—The superior surface of the cerebellum is somewhat elevated in the middle line and sloped toward its circumference, its hemispheres being connected together by an elevated median portion or lobe, the *superior worm* or *superior vermiform process*. The surface is traversed by four curved fissures, which are named from their situation, in front or behind two prominent lobes of the worm, the central lobe and the clivus. (1) the pre-central fissure, (2) the post-central fissure, (3) the pre-clival fissure, and (4) the post-clival fissure. These four fissures divide the entire upper surface of the cerebellum into five lobes, but the portion of the lobe in the worm has received a different name from that in the hemisphere, though the two are continuous with each other. The five lobes in the worm are named from before backward: (1) the *lingula*, (2) the *lobulus centralis*, (3) the *culmen monticuli*, (4) the *clivus monticuli*, and (5) the *folium caecuminis*. The five lobes in the hemispheres are named from before backward: (1) the *frænum*, (2) the *ala lobuli centralis*, (3) *anterior crescentic*, (4) *posterior crescentic*, and (5) *posterior superior*. The arrangement of these fissures and lobules will be understood by reference to the accompanying schematic arrangement, in which the lobules are named in order from before backward with the fissures which separate them:

UPPER SURFACE OF THE CEREBELLUM.

<i>Worm.</i>	<i>Hemisphere.</i>
Lingula.	Frænulum.
	<i>Pre-central fissure.</i>
Lobulus centralis.	Ala lobuli centralis.
	<i>Post-central fissure.</i>
Culmen monticuli.	Anterior crescentic lobe.
	<i>Pre-clival fissure.</i>
Clivus monticuli.	Posterior crescentic lobe.
	<i>Post-clival fissure.</i>
Folium cacuminis.	Posterior superior lobe.

The **lingula** is a tongue-shaped process of the cerebellum, which lies in front of the lobulus centralis and is partially or completely concealed by it. It is in relation, in front, with the valve of Vieussens, on the dorsal surface of which it rests and with which it is connected; its white matter being continuous with that of the valve. At either side the lingula gradually shades off, and is prolonged only for a short distance into the hemispheres, where it forms the **frænulum**. This does not stretch beyond the superior peduncle of the cerebellum over which it lies.

The Lobulus Centralis.—The lobulus centralis is a small square lobe, situated in the anterior notch. It overlaps the lingula and is in turn partially concealed by the culmen monticuli. Laterally the lobulus centralis extends along the upper and anterior part of each hemisphere, where it forms a wing-like prolongation, the **ala lobuli centralis**.

The **culmen monticuli** is much larger than the two lobes just described, and constitutes, with the succeeding lobe, the clivus, the bulk of the upper worm. In front it partially overlaps and obscures the lobulus centralis, and behind it is separated from the clivus by the *pre-clival fissure*. It forms the most prominent part of the upper worm, and is marked on its surface by three or four secondary fissures, dividing it up into smaller lobules. Laterally it is continuous with the **anterior crescentic lobe** of the hemispheres, which is distinctly differentiated from the posterior crescentic lobe by the *pre-clival fissure*, though the two were formerly classed together as the quadrate lobe of the lateral hemisphere.

The **clivus monticuli** is of considerable size, and, as stated above, forms with the culmen the major part of the superior worm. It consists of a group of laminae, which in front are separated from the culmen by the *pre-clival fissure* and behind appear to be almost continuous with the folium cacuminis, especially in the median line; but it will be found, on careful examination, to be separated from it by a well-defined fissure, the *post-clival fissure*. Laterally this lobe is continued into the hemispheres as the **posterior crescentic lobe**, which is somewhat semilunar in shape, and, with the anterior crescentic lobe, constitutes the greater part of the upper surface of the hemispheres.

The **folium cacuminis** is a short and narrow, concealed band at the posterior extremity of the worm, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally it expands in either hemisphere into a considerable lobe, which is semilunar in shape, and is situated at the postero-superior part of the hemisphere and bounded below by the great horizontal fissure. It is named the **posterior superior lobe** and occupies the posterior third of the upper surface of the hemisphere, forming its rounded postero-lateral border.

The **Under Surface of the Cerebellum** (Fig. 364) presents in the middle line the *inferior worm*, buried in the vallecule, and separated from the hemispheres by

lateral grooves. Here, as on the upper surface, there are deep fissures, dividing it into separate segments or lobes, but the arrangement is more complicated, and the relation of the segments of the worm to those of the hemisphere is less clearly marked. The fissures are three in number, but are not so regularly disposed as

FIG. 364.—Under surface of the cerebellum. (Schäfer.)

those on the upper surface (Fig. 365). They are named, from their relation to the pyramid and nodule, two of the lobes on the under surface of the worm, (1) *post-nodular*, (2) *pre-pyramidal*, and (3) *post-pyramidal* fissures. The part of the worm in front of the post-nodular fissure is termed the *nodule*, and the lobule in the hemisphere corresponding with this is the *flocculus*. The next lobe is situated between

FIG. 365.—Diagram showing fissures on under surface of the cerebellum: F, flocculus; N, nodule; U, uvula; Py., pyramid; Am., amygdala; Bivent., biventral lobe.

the post-nodular and pre-pyramidal fissures. In the vermiform process it is known as the *uvula*, and its lateral expansion in the hemisphere is named the *amygdala* or *tonsil*. The lobule of the worm between the pre- and post-pyramidal fissures is the *pyramid*, and its corresponding part in the hemisphere is the *biventral* or *digastric* lobe. Finally, behind the post-pyramidal fissure in the worm is a small lobe, the *tuber valvulæ* or *tuber posticum*; this, in the hemispheres, expands into a large lobe, which occupies at least two-thirds of the inferior surface of the cerebellum, and is subdivided into two by a secondary fissure, named the *post-gracile*

fissure. The anterior of the two subdivisions is named the *slender lobe*; and the posterior, the *inferior semilunar* or *posterior inferior lobe*. These fissures and lobes are here arranged, from before backward, in a schematic form :

UNDER SURFACE OF THE CEREBELLUM.

Worm.	Hemisphere.
Nodule.	Flocculus.
<i>Post-nodular fissure.</i>	
Uvula.	Amygdala.
<i>Pre-pyramidal fissure.</i>	
Pyramid.	Biventral lobe.
<i>Post-pyramidal fissure.</i>	
Tuber valvulæ.	{ Slender lobe. { <i>Post-gracile fissure.</i> { Inferior semilunar lobe.

The chief fissures of the under surface, as stated above, are three in number, and are not so regularly disposed as on the upper surface. (1) The *post-nodular fissure* in the worm courses transversely across it, separating the nodule in front from the uvula behind. When it reaches the hemispheres it passes in front of the amygdala, and then crosses between the flocculus in front and the biventral lobe behind, and joins the anterior end of the great horizontal fissure. (2) The *pre-pyramidal fissure* crosses the worm between the uvula in front and the pyramid behind, then curves laterally behind the amygdala, and passes forward along the outer border of this lobe, between it and the biventral lobe, to join the post-nodular sulcus. (3) The *post-pyramidal fissure* passes across the worm behind the pyramid and in front of the tuber valvulæ, and in the hemispheres courses behind the amygdala and biventral lobes, and then along the outer border of the biventral lobe to the post-nodular sulcus. It cuts off at least two-thirds of the inferior surface of the hemisphere. From it a secondary sulcus springs, and coursing forward and outward divides this surface into two parts and falls into the great horizontal fissure. This sulcus is termed the *post-gracile fissure*.

THE LOBES OF THE INFERIOR SURFACE OF THE CEREBELLUM.

The Nodule and Flocculus.—The nodule is a distinct prominence, forming the anterior extremity of the inferior worm. It projects into the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla and pons. On each side of the nodule is a thin layer of white substance, named the *inferior medullary velum*. It is semilunar in form, its convex border being continuous with the white substance of the cerebellum; it extends on either side as far as the flocculus, which it connects with the nodule. The flocculus is a prominent, irregular lobule, situated just in front of the biventral lobe, between it and the middle peduncle of the cerebellum. It is subdivided into a few small laminae, and is connected to the inferior medullary velum by its central white core.

The Uvula and Amygdalæ.—The uvula occupies a considerable portion of the inferior worm; it is separated on either side from the amygdala by a deep groove, the *sulcus vallecule*, at the bottom of which it is connected to the amygdala by a commissure of gray matter, indented on its surface, and called the *furrowed band*. It is marked on its surface by three or four transverse fissures. The amygdalæ, or tonsils, are rounded masses, situated in the lateral hemispheres. Each lies in a deep fossa between the uvula and the biventral lobe; this fossa is known by the name of the *bird's nest* (*nidus avis*).

The Pyramid and Biventral Lobes.—The pyramid is a conical projection, forming the largest prominence of the lower worm. It is separated from the hemispheres by the sulcus vallecule, across which it is connected to the biventral lobe by an indistinct band of gray matter, analogous to the furrowed band already described. The biventral lobe is triangular in shape, with the apex pointing inward and backward to become joined by the connecting band to the pyramid. The external border is separated from the slender lobe by the post-pyramidal fissure. The base is directed forward, and is on a line with the anterior border of the amygdala, and is separated from the flocculus by the post-nodular fissure.

The Tuber Valvulæ or Tuber Posticum, and Posterior Inferior Lobes.—The tuber valvulæ is the posterior division of the inferior worm. It is of small size, and laterally spreads out into the large posterior inferior lobes of the hemispheres. These lobes, which, as stated above, comprise at least two-thirds of the inferior surface of the hemisphere, are divided into two by the post-gracile fissure. The anterior lobe is named the *slender lobe*, and the posterior, the *inferior semilunar lobe*. Both these lobes show a tendency to subdivision into two; that of the slender lobe is well marked, and its subdivisions are sometimes described as distinct lobes and named the *anterior* and *posterior slender lobes*, the fissure between them being termed the *intra-gracile fissure*.

INTERNAL STRUCTURE OF THE CEREBELLUM.

The cerebellum consists of white and gray matter.

The White Matter.—If a sagittal section (Fig. 366) is made through either hemisphere of the cerebellum, the interior will be found to consist of a central stem of white matter, which contains in its interior a gray mass, the *corpus dentatum*. From the surface of this central stem a series of plates of medullary matter are detached, which, covered with gray matter, form the laminae. In consequence of the main branches from the central stem dividing and subdividing, the section presents a characteristic appearance, which is named the *arbor vitæ*. If a vertical section is made in the median plane of the cerebellum it will be found that the central stem divides into two main branches, which, from their direction, may be named respectively the vertical and the horizontal branch. The *vertical* branch passes upward to the culmen, where it subdivides freely, some of its ramifications passing forward and upward to the central lobe. The *horizontal* branch passes backward to the folium cacuminis, considerably diminished in size in consequence of having given off large secondary branches: one, from its upper surface, ascends to the clivus; the others descend, and enter the lobes in the inferior vermiform process, the tuber valvulæ, the pyramid, the uvula, and the nodule. It is not necessary to describe in detail the various divisions of the white matter, as they correspond to the lobes on the surface.

The white matter of the cerebellum includes two varieties of nerve matter: (1) the *peduncular fibres*, which are directly continuous with those of the peduncles of the cerebellum; (2) the fibres proper (*fibræ propriæ*) of the cerebellum itself.

The Peduncles of the Cerebellum.—From the anterior part of each hemisphere arise three large processes or peduncles—superior, middle, and inferior—by which the cerebellum is connected with the rest of the encephalon.

The **superior peduncles** form the upper lateral boundaries of the floor of the fourth ventricle. As they extend forward and upward they converge on the dorsal aspect of the ventricle, and thus assist to roof it in. They may be traced as far as the corpora quadrigemina, under which they pass. They enter the upper and mesial part of the medullary substance of the hemispheres, beneath the ala lobuli centralis and the frænulum, and pass to a great extent into the interior of the corpus dentatum, though some of their fibres wind round it and reach the gray cortical matter, especially of the inferior surface.

The fibres of the superior peduncles mainly emerge from the hilum of the corpus

dentatum; others come from the cortex and probably also from the smaller nuclei in the central white substance. The majority of the fibres decussate with those of the opposite peduncle below the corpora quadrigemina, and pass to the red nucleus of the tegmentum, from which a relay is prolonged through the optic thalamus to the cerebral cortex. Fibres also connect the spinal cord with the cerebellum through its superior peduncles; these are chiefly derived from the antero-lateral ascending cerebellar tract of Gowers.

The Valve of Vieussens or Superior Medullary Velum.—Stretched across from one superior peduncle to the other is a thin, transparent lamina of white matter, the *valve of Vieussens*; on to the dorsal surface of its lower half the folia of the lingula are prolonged. It forms with the superior peduncles the roof of the upper part of the fourth ventricle, and is continuous with the central white stem of the cerebellum. It is narrow above, where it passes beneath the corpora quadrigemina, and broader below, at its connection with the white substance of the superior worm of the cerebellum. A slight elevated ridge descends upon the upper part of the valve from between the lower corpora quadrigemina, and on either side of this may be seen the fourth nerve.

FIG. 366.—Sagittal section of the cerebellum, near the point of junction of the worm with the hemisphere. (Schäfer.)

The **middle peduncles** are the largest of the three pairs. They consist of a mass of curved fibres, which, as already described, comprises most of the transverse fibres of the pons. They enter the cerebellum between the margins of the great horizontal fissure at the anterior notch, and the fibres spread out in all directions: some passing to the upper part, and some to the lower part of the hemisphere, while others pass to its middle region. Of the fibres contained in the middle peduncles many are commissural between the two hemispheres of the cerebellum; others apparently end in the gray matter; others have been described as giving fibres to the posterior longitudinal bundle, and through it to the nuclei of the third, fourth, and sixth nerves. Cajal describes still another set, which have their origin in the gray reticular formation of the pons, and which pass partly into the peduncle of the same side and partly into that of the opposite side.

The **inferior peduncles** connect the cerebellum with the medulla oblongata. As the restiform bodies of the latter, they will be described in the sequel. They pass upward and outward, forming part of the lateral wall of the fourth ventricle, and

enter the cerebellum beneath the middle peduncle; passing upward they end in the gray cortex of the upper surface of the hemisphere, some being prolonged into the white matter of the superior vermiciform process. The following are the chief sets of fibres in the inferior peduncles: (1) from the direct cerebellar tract of the spinal cord; (2) from the gracile and cuneate nuclei (crossed and uncrossed fibres); (3) from the opposite olivary body of the medulla; (4) fibres to the nuclei of the fifth, eighth, ninth, and tenth nerves; (5) descending cerebellar fibres which pass down the restiform body and antero-lateral column of the cord to terminate around the cells in the anterior horn of the cord.

The *fibræ propriæ* of the cerebellum are of two kinds: (1) *commissural fibres*, which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part, and others at the posterior part of the vermiciform process; (2) *arcuate or association fibres*, which connect adjacent laminæ with each other.

The gray matter of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

1. The gray matter of the cortex presents a characteristic foliated appearance, due to the series of laminæ which are given off from the central white matter; these in their turn give off secondary laminæ, which are covered with gray matter. This

FIG. 367.—Diagrammatic representation of the cells of the cerebellum. (Modified from Foster's "Physiology.") A, molecular layer; B, nuclear layer; C, white matter.

arrangement gives to the cut surface of the organ a foliated appearance (Fig. 366). Externally, the cortex is covered by pia mater; internally, is the medullary centre, consisting mainly of nerve-fibres.

Microscopic Appearance of the Cortex.—The cortex presents a remarkable structure, consisting of two distinct layers, viz., an external gray molecular layer, and an internal, rust-colored, granular layer. Between the two layers is an incomplete stratum of the characteristic cells of the cerebellum, the *corpuscles of Purkinje*.

The *external gray* or *molecular layer* (Figs. 367, 368) consists of fibres and cells. The nerve-fibres are delicate fibrillæ, and are derived from the following sources: (a) the dendrites and axon collaterals of Purkinje's cells; (b) fibres from cells in the granular layer; (c) fibres from the central white substance of the cerebellum; (d) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction. These are the processes of large glia-cells, situated in the granular layer. They pass outward to the periphery of the gray matter, where they expand into little conical enlargements, which form

a sort of limiting membrane beneath the pia mater, analogous to the *membrana limitans interna* in the retina, formed by the fibres of Müller.

The *cells* of the molecular layer are small, and are arranged in two strata, an outer and an inner. They all possess branching axis-cylinder processes; those of the inner layer run for some distance horizontally, *i. e.*, parallel with the surface of the folia, giving off at intervals collaterals, which pass in a vertical direction toward the cell-bodies of Purkinje's corpuscles, around which they become enlarged, and ramify like a basket. Hence these cells of the inner layer are named *basket-cells*.

The *corpuscles of Purkinje* (Fig. 368) are flask-shaped cells, situated at the junction of the molecular and granular layers, their bases resting against the latter.

FIG. 368.—Vertical section through the gray matter of the human cerebellum. Magnified about 100 diameters. (Klein and Noble Smith.)

From the bottom of the flask the axis-cylinder process arises; this passes through the granular layer, and, becoming medullated, is continued as a nerve-fibre in the medullary substance beneath. This axon gives off fine collaterals as it passes through the granular layer, some of which run back into the molecular layer. From the neck of the flask numerous dendrites are given off, which branch in an antler-like manner in the molecular layer and terminate in free extremities.

The *internal rust-colored* or *granular layer* (Fig. 368) is characterized by containing numerous small nerve-cells or granules of a reddish-brown color, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with

short dendrites, which spread out in a spider-like manner in the granular layer. Their axons pass outward into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are also to be observed some larger cells, of the type termed *Golgi cells* (Fig. 367). Their axons undergo frequent division as soon as they leave the nerve-cells, and pass into the granular layer, while their dendrites ramify chiefly in the molecular layer.

Finally, in the gray matter of the cerebellar cortex fibres are to be seen which come from the white centre and penetrate the cortex. The cell origin of these fibres is unknown, though it is believed that it is probably in the gray matter of the spinal cord. Some of these fibres end in the granular layer, by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the "moss fibres"; they form an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells, and hence they have been named the *clinging* or *tendrill fibres*.

2. The independent centres of gray matter in the cerebellum are four in number on each side: one is of large size, and is known as the corpus dentatum; the other three, much smaller, are situated near the middle of the cerebellum, and are known as the nucleus emboliformis, nucleus globosus, and nucleus fastigii.

The *corpus dentatum* or *ganglion of the cerebellum* is situated a little to the inner side of the centre of the stem of the white matter of the hemisphere. It consists of an irregularly folded lamina of a grayish-yellow color, containing white fibres, and presenting on its antero-internal aspect an opening, the hilum, from which most of the fibres of the superior cerebellar peduncle emerge.

The *nucleus emboliformis* is a mass of gray matter placed immediately to the inner side of the corpus dentatum, and partly covering its hilum. The *nucleus globosus* is an elongated mass of gray matter, directed antero-posteriorly, and placed to the inner side of the preceding. The *nucleus fastigii* is somewhat larger than the other two, and is situated close to the middle line at the anterior end of the superior vermiform process, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white matter. It is known as the *roof nucleus of Stilling*.

Weight of the Cerebellum.—Its average weight in the male is about 5 oz., 4 drs. It attains its maximum weight between the twenty-fifth and fortieth years, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to 8½, and in the female as 1 to 8. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13, and 1 to 26; by Cruveilhier the proportion was found to be 1 to 20.

V. The Medulla Oblongata (Fig. 370).

The *medulla oblongata* or *metencephalon*, known also as the *spinal bulb*, is the lowest division of the encephalon, and is continuous with the spinal cord. It is developed from the fifth cerebral vesicle, the cavity of which forms the lower half of the fourth ventricle. It extends from the lower margin of the pons Varolii to a plane passing transversely just below the decussation of the pyramids, at which level the spinal cord commences. This plane corresponds to the lower margin of the foramen magnum. The upper limit of the medulla is marked off from the pons Varolii on its ventral aspect by the abrupt lower margin of the latter.

The *medulla oblongata* is directed from above obliquely downward and backward; its ventral surface rests on the basilar groove of the occipital bone, while its dorsal surface is received into the fossa between the hemispheres of the cerebellum, and forms the lower part of the floor of the fourth ventricle. It is pyramidal

in shape, its broad extremity directed upward, its lower end being narrow at its point of connection with the cord. It measures an inch in length, three-quarters of an inch in breadth at its widest part, and half an inch in thickness. Its surface is marked, in the median line, in front and behind, by an *anterior* and a *posterior*

median fissure, which are continuous with similar fissures on the anterior and posterior surfaces of the cord. The anterior fissure contains a fold of pia mater, and terminates just below the pons in a *cul-de-sac*, the *foramen cæcum* of Vicq d'Azyr. It is interrupted at its lower part by some bundles of fibres, which cross obliquely from one side to the other, forming the *decussation of the pyramids*. The posterior is a deep but narrow fissure, continued upward to about the middle of the medulla, where it expands into the fourth ventricle.

These two fissures divide the medulla into two symmetrical halves, each half presenting elongated eminences, which are continuous with the columns of the cord. By taking the lines along which some of the cranial nerves emerge from the medulla, as landmarks, the surface of this portion of the

FIG. 369.—Medulla oblongata and pons Varolii. Anterior surface.

nervous system may be divided into three columns, in the same way as the spinal cord is divided into three columns by the lines corresponding to the points of exit of the anterior and posterior roots of the spinal nerves. The anterior column comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve: this column is called the *pyramid*. The lateral column comprises that portion which is situated between the fibres of origin of the hypoglossal nerve and the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. In the lower part of the medulla this column is single, and is called the *lateral tract*; but in the upper part an oval-shaped body comes forward between it and the pyramid, and pushes aside the lateral tract. This is called the *olivary body*. The posterior column comprises that portion which is situated between the fibres of the origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves and the posterior median fissure. It is marked by slight furrows dividing it into smaller columns, and these in the lower part of the medulla are named, from without inward, the *funiculus of Rolando*, the *funiculus cuneatus*, and the *funiculus gracilis*; in the upper part of the medulla, the funiculus of Rolando and the funiculus cuneatus appear to become fused together, forming a single body, called the *restiform body* (Fig. 370).

The *pyramids* are two pyramidal bundles of white matter, placed one on either side of the anterior median fissure, and separated from the olivary body by a slight depression, from which the roots of the hypoglossal nerve emerge. At the lower border of the pons these bodies are somewhat constricted and are here crossed by a band of arched fibres, the *ponticulus* of Arnold; below this they become enlarged, and then taper as they descend to their lower extremity. The fibres of which these pyramids are composed may be arranged in two bundles: an outer, continuous below with the direct pyramidal tract of the anterior column of the same side of the spinal cord, and an inner, continuous with the crossed pyramidal tract of the lateral column of the opposite side of the cord. As will be subsequently mentioned, the direct pyramidal tract in the cord lies next to the anterior median fissure, but as the crossed pyramidal tract of the cord ascends to the medulla it decussates with its fellow of the opposite side across the anterior median fissure, and so displaces laterally the direct pyramidal tract, and ascends, after decus-

sation, through the medulla to its inner or mesial side. This decussation is usually spoken of as the *decussation of the pyramids*, but it must be borne in mind that it is only a portion of the fibres of the pyramid which decussate; namely, those derived from the crossed pyramidal tract of the cord; the outermost fibres, derived from the anterior column of the cord, do not decussate. Each pyramid enters the substance of the pons in one bundle, and may be traced through it, after breaking up into several smaller fasciculi, into the corresponding crus cerebri.

The **lateral column**, in the lower part of the medulla, is of the same width as the lateral column of the cord, and appears on the surface to be a direct continuation of it. As a matter of fact it is only a part of the lateral column of the spinal cord which is continued upward into this column; for the crossed pyramidal tract passes into the pyramid of the opposite side, and the direct cerebellar tract of the lateral column of the cord passes into the restiform body. The rest of the lateral column of the cord, that is to say, the antero-lateral ground bundle and the antero-lateral cerebellar tract, can be traced upward into this area. In the upper part of the medulla, the lateral tract, on account of the interpolation of the olivary body, becomes almost concealed by this body.

The **olivary body** is a prominent oval mass, situated on the outer side of the pyramid, from which it is separated by a slight groove, along which the fibres of the hypoglossal nerve emerge. It is separated externally from the restiform body by a longitudinal, narrow band of fibres, prolonged upward from the lateral tract, and by a groove, from which the glosso-pharyngeal, pneumogastric, and spinal accessory nerves arise. It is equal in breadth to the pyramid; it is broader above than below, and is about half an inch in length, being separated above from the pons Varolii by a slight depression, in which a band of arched fibres is sometimes to be seen. Numerous white fibres (*superficial arciform fibres*) are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body.

The **funiculus of Rolando** is a longitudinal prominence on the outer side of the lateral tract. It begins at the lower end of the medulla by a tapering extremity, and has, apparently, no corresponding column in the cord. It gradually enlarges as it ascends, and forms, at a level with the lower border of the olivary body, a considerable prominence, known as the *tubercle of Rolando*. This is caused by the substantia gelatinosa of Rolando of the cord gradually finding its way to the surface, so as to form a prominence there. About half an inch below the pons the funiculus of Rolando appears to blend with the funiculus cuneatus. In front, it is separated from the lateral tract by a distinct groove, the continuation upward of the postero-lateral groove of the cord; behind, the separation from the funiculus cuneatus is much less distinct.

The *funiculus cuneatus* is the direct continuation upward of the postero-lateral column (tract of Burdach) of the cord. It is situated between the funiculus of Rolando and the funiculus gracilis. It enlarges as it ascends, and forms, opposite the lower extremity of the fourth ventricle, a slight eminence or enlargement, the

FIG. 370.—Posterior surface of the medulla oblongata.

cuneate tubercle, which is best marked in children. Above this point it disappears from the surface.

The *funiculus gracilis* is the direct continuation upward of the postero-median column of the cord (tract of Goll). It is a narrow white band, placed parallel to and along the side of the posterior median fissure. It is separated from the *funiculus cuneatus* by a slight groove, continuous with that on the surface of the cord, which marks off the postero-median column. At first the funiculi of the two sides lie in close contact on either side of the posterior median fissure. Opposite the apex of the fourth ventricle each presents an enlargement, the *clava*; they then diverge and form the lateral boundaries of the lower part of the fourth ventricle, and gradually tapering off become no longer traceable.

The Restiform Body.—The upper part of the posterior area of the medulla is occupied by the *restiform body*. It appears, at first sight, as if this body were the direct continuation upward of the *funiculus cuneatus* and the *funiculus of Rolando*, and it was formerly described as such. This, however, is not so, for the restiform body is largely formed by a set of fibres, the *external arcuate fibres*, which issue from the anterior median fissure and will presently be described. They pass laterally over the pyramid and olive, and assist in forming the restiform body. There is also a narrow strand of fibres, derived from the lateral column of the cord, the *direct cerebellar tract*, which joins the above-mentioned arcuate fibres. These two sets of fibres, reinforced by the *internal arcuate fibres* from the opposite side of the medulla, form the restiform body.

The restiform bodies are the largest prominences of the medulla, and are placed between the lateral tracts in front and the *funiculus cuneatus* behind, from both of which they are separated by slight grooves. As they ascend they diverge from each other, assist in forming the lower part of the lateral boundaries of the fourth ventricle, and then enter the corresponding hemisphere of the cerebellum, forming its inferior peduncles.

The posterior surface of the *medulla oblongata* forms part of the floor of the fourth ventricle. This portion is of a triangular form, bounded on each side by the diverging funiculi *graciles* and *cuneati* and restiform bodies. The divergence of these two funiculi and of the restiform bodies, together with the opening out of the posterior fissure and central canal of the spinal cord, displays in the floor of the ventricle the gray matter of the medulla, which is continuous below with the gray matter of the cord. In the middle line is seen a longitudinal furrow, which divides this part of the ventricle into right and left halves, and is continuous below with the central canal of the cord.

The *arciform* or *arcuate fibres*, which have been mentioned as forming part of the restiform body, are found in the upper half of the medulla, crossing its surface and also traversing its substance. They are divided for purposes of description into two sets—external and internal. The *external* or *superficial arciform fibres* have already been alluded to as crossing the pyramid and olivary body on each side. They emerge from the anterior median fissure, and if traced into it are found to enter the *raphé* and cross to the opposite side, after which their further course is a matter of some doubt. After emerging from the anterior median fissure they cross the pyramid and olivary body, often concealing from view the upper part of the *cuneate* and *Rolandic funiculi*, and enter the restiform body. As they cross the olivary body they are reinforced by some of the internal arciform fibres, which come to the surface on the inner side of, or through, this structure. The *internal arciform fibres* are described with the microscopic anatomy of the medulla.

It is advisable, at this stage, to take up the consideration of the cavity of the fourth ventricle, an acquaintance with which will render the description of the internal structure of the *medulla oblongata* more intelligible.

The Fourth Ventricle (Fig. 371).

The fourth ventricle is lozenge- or diamond-shaped; that is to say, it is composed of two triangles, with their bases in contact. The sides of the lower triangle are formed by the divergence of the funiculi graciles, funiculi cuneati, and restiform bodies of the medulla on either side. As these columns pass upward in the medulla they turn outward from the median line, and, diverging from each other, form the lateral boundaries of the lower half of the fourth ventricle. In like manner the sides of the upper triangle are formed by the convergence of the superior peduncles of the cerebellum. These peduncles are separated below by a somewhat wide interval, but as they pass upward and forward toward the corpora quadrigemina they gradually converge and ultimately come into contact with each other. This cavity is therefore bounded laterally by the superior peduncles of the cerebellum in its upper half, and by the funiculi graciles, the funiculi cuneati, and the restiform bodies in its lower half. It presents four angles. The upper angle reaches as high as the upper border of the pons, and corresponds with the lower opening of the aqueduct of Sylvius, by which this ventricle communicates with the third ventricle. The lower angle is on a level with the lower border of the olivary body, and is continuous with the central canal of the spinal cord. From the resemblance that it bears to the point of a writing pen it has been named the *calamus scriptorius*. Its lateral angles extend for some distance between the medulla and the cerebellum, each forming a pointed *lateral recess*.

The *roof* of the fourth ventricle is formed from above downward by the following structures: a part of the superior peduncles of the cerebellum, the superior medullary velum, the inferior medullary velum, the tela choroidea inferior, the obex, and the ligula.

The **superior peduncles of the cerebellum**, when they emerge from the medullary substance of its hemispheres, pass upward and forward, forming the lateral boundaries of the upper half of the fourth ventricle, but, converging as they approach the corpora quadrigemina, the mesial portions of the peduncles form a part of the roof of the cavity, in consequence of the ventricle extending to a slight extent underneath the peduncles.

The Superior Medullary Velum (Valve of Vieussens).—In the angular interval left between the two superior peduncles is a thin lamina of white matter, continuous with the white centre of the cerebellum, which bridges across from one peduncle to the other, and so completes the roof of the superior part of the ventricle. This is the *superior medullary velum*, or *valve of Vieussens*. Its dorsal surface is covered by the folia of the lingula, already described (page 686).

The **inferior medullary velum** is a thin layer of white substance, prolonged from the white centre of the medulla on either side of the nodule, which assists in forming a part of the roof of the fourth ventricle, stretching over it toward its lateral angles. It is continuous with the white substance of the cerebellum by its convex edge, while its thin concave margin is apparently free. In reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downward from the velum to the edge of the ligula.

The **tela choroidea inferior** is a layer of pia mater, which covers in the lower part of the fourth ventricle below the inferior medullary velum. Superiorly it is reflected on to the under surface of the cerebellum, while inferiorly it is continued on to the restiform bodies and lower part of the medulla. This part of the roof of the ventricle contains no nervous matter, but consists merely of the ventricular epithelium covered by pia mater. The tela choroidea inferior, like the superior, really consists of two layers, which become more or less adherent, viz., that covering the under surface of the cerebellum and that covering the epithelium. It also possesses a pair of choroid plexuses, which project into the ventricular cavity invaginating before them the epithelial lining. Each plexus consists of a *vertical* portion which extends forward, near the middle line, from the

foramen of Majendie, and of a *transverse* part, which passes outward into the lateral recess of the ventricle as far as the foramina of Key and Retzius. The two plexuses present the form of a T, the vertical limb of which is, however, double, . The tela does not form a complete membrane, for in it there are three openings, one in the middle line at the inferior angle of the ventricle, just above the position of the opening of the central canal of the cord; this is the *foramen of Majendie*: the other two are at the extremities of the lateral recesses of the ventricle, and are named the *foramina of Key and Retzius* (see page 642). Through these foramina the ventricles of the brain communicate with the subarachnoid space.

The *obex* is a thin triangular lamina of gray matter, continuous below with the anterior gray commissure of the cord, which fills in the angle between the two diverging funiculi graciles for a short distance.

The *ligula (tæniæ)* are narrow bands of white matter, which project from the internal border of the funiculi graciles. They at first run upward and forward,

FIG. 371.—Floor of the fourth ventricle. Diagrammatic.

and then turn outward over the restiform bodies, as far as the lateral recesses of the ventricle. Their inner borders are continuous with the epithelial roof of the ventricle.

The floor of the fourth ventricle (Fig. 371) is rhomboidal in shape, and is traversed by a vertical median fissure, the *sulcus longitudinalis medianus*. At its widest part, opposite the level of the lateral recesses, it is marked by some transverse white lines, the *striæ medullaris* or *striæ acusticæ*. These consist of white fibres, which emerge from the longitudinal sulcus, and pass outward across the floor of the ventricle.

These striæ divide the floor of the ventricle into two triangles, inferior and superior. The *inferior triangle*, or lower half of the floor, presents above an angular groove, the *fovea inferior*, the apex of which is at the striæ, while the two limbs diverge below, and form the sides of a triangular, dark area, termed the *ala cinerea*, which becomes elevated into a prominence below (*eminentia cinerea*). This area corresponds with the nuclei of the vagus and glosso-pharyngeal nerves, and is therefore termed the *trigonum vagi*. A second triangular area lies between the inner limb of the fovea and the median sulcus; its base is directed

upward, and limited by the *striæ medullaris*. It is termed the *trigonum hypoglossi*, because it corresponds in position to the tract of nerve-cells from which the hypoglossal nerve takes origin. A third triangular area to the outer side of the fovea inferior, is named the *trigonum acustici*. It lies between the groove forming the outer boundary of the fovea inferior and the lateral wall of the ventricle, and, like the *trigonum hypoglossi*, has its base directed upward. Here it is continuous with a prominence, the *tuberculum acusticum*, which extends into the anterior part of the floor of the ventricle.

The *superior triangle*, or upper half of the floor of the fourth ventricle, *i. e.*, the part above the *striæ medullaris*, presents in the middle line the continuation of the median longitudinal sulcus. On either side of this is a spindle-shaped longitudinal eminence, prominent in its centre, but less so above and below. This is the *eminentia teres*, and is produced by an underlying bundle of white fibres, the *funiculus teres*, formed, in part at all events, by the fibres of the facial nerve. Immediately above and to the outer side of the *eminentia teres* is an angular depression, the *fovea superior*; this is sometimes crossed by a whitish band of fibres, the *conductor sonorus*, which is connected below with the *striæ medullaris*. Above the fovea is a bluish depressed area, the *locus ceruleus*. Its color is due to some pigmented nerve-cells, showing through the white covering of the floor. These pigmented cells are named the *substantia ferruginosa*, and in them one of the roots of the fifth nerve terminates.

The lining membrane of the fourth ventricle is continuous above with that of the third, through the aqueduct of Sylvius, and below with that of the central canal of the spinal cord. The cavity of the ventricle communicates below with the subarachnoid space by means of the foramen of Majendie and the foramina of Key and Retzius, already described.

Internal Structure of the Medulla Oblongata (Fig. 372).

If the cranial nerves emerging from the medulla are traced into its substance, it will be seen that they divide each half into three wedge-shaped areas, which are named the anterior, lateral, and posterior areas of the medulla, and each of which corresponds to one of the subdivisions already described on the surface of this portion of the encephalon.

The **anterior area** comprises that portion which is situated between the anterior median fissure and the fibres of origin of the hypoglossal nerve. On the surface of the medulla this area corresponds to the pyramid.

The **lateral area** is situated between the fibres of origin of the hypoglossal nerve on the one hand, and the fibres of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves on the other. On the surface of the medulla, in its lower part, this area is single, and is called the *lateral tract*; but in the upper part an oval-shaped body, the *olivary body*, comes forward between it and the pyramid, pushing aside the lateral tract.

The **posterior area** comprises that portion which is situated between the fibres of origin of the glosso-pharyngeal, pneumogastric, and spinal accessory nerves, and the posterior median fissure. On the surface of the medulla this area is marked by slight furrows, splitting it up into smaller columns; those in the lower part of the medulla are named, from without inward, the *funiculus of Rolando*, the *funiculus cuneatus*, and the *funiculus gracilis*; in the upper part of the medulla they are replaced by the restiform body. Finally, the halves of the medulla are separated from each other by a median septum or *raphé*.

Each of these three areas is made up of gray and white matter, the former being derived for the most part from that of the cord. In like manner the white matter is partly made up of longitudinal fibres continuous with those of the cord, and partly of transverse fibres which intersect them.

In order to understand the internal structure of the medulla, it is necessary to

describe the appearances as they are seen in the upper and lower portions of the medulla, since they differ considerably in these two parts.

The Lower Part of the Medulla.—The first change in the internal structure is caused by the passage of the fibres of the crossed pyramidal tract obliquely through the gray matter of the anterior horn. As stated above, the pyramid is composed of fibres derived from the direct pyramidal tract of the anterior column of the cord of the same side, and from the crossed pyramidal tract of the lateral column of the opposite half of the cord. Those fibres which are derived from the direct pyramidal tract and which in the cord lie close to the median fissure are in the medulla placed to the outer side of the pyramid, being pushed aside, as it were, by the interpolation of the fibres derived from the crossed pyramidal tract, which are much more numerous. The crossed pyramidal fibres ascend from the lateral column of the spinal cord, and, passing through the anterior gray cornu and across the middle line, form the inner part of the pyramid. In consequence of this passage of white fibres through its substance the anterior gray cornu is

FIG. 372.—Section of the medulla oblongata at about the middle of the olivary body. (Schwalbe.)

broken up into a coarse network, while one portion of it, the caput cornu, is entirely separated from the rest; only the base of the cornu remains intact, close to the ventro-lateral aspect of the central canal. The caput cornu, thus separated, is displaced laterally, and comes to lie close to the caput cornu posterioris, which has also shifted its position. In consequence of this breaking up of the greater part of the anterior gray cornu by white fibres a coarse network is formed in the anterior and lateral areas of the medulla, which is named the *formatio reticularis*.

The posterior cornu also undergoes somewhat similar changes. It becomes subdivided by the passage through it of the sensory fibres of the columns of Goll and Burdach. These pass across to the opposite anterior area of the medulla, where they are seen to lie immediately on the dorsal aspect of the pyramids. In their passage through the posterior horns of gray matter the latter become subdivided, in a manner somewhat similar to what has been seen to occur in the anterior horns. This crossing of the sensory fibres is termed the *superior pyram-*

idal or *sensory decussation*. The caput cornu is displaced outward, so as almost to reach the surface, where it forms a projection, the *funiculus Rolando*, which enlarges above into a distinct prominence, the *tubercle of Rolando*. Above the level of the tubercle of Rolando the caput cornu is separated from the surface by a band of fibres, termed the *ascending root of the fifth nerve*, and by the external arcuate fibres. The neck of the cornu becomes broken up into a reticular formation by the decussation of the columns of Goll and Burdach, and by this means the caput is separated from the rest of the gray matter. The base of the cornu increases in size, and, as the central canal expands into the fourth ventricle, becomes pushed outward, and portions of it extend into the funiculi graciles and cuneati, and produce externally the eminences of the clava and cuneate tubercle. A third portion of the base becomes separated from the rest, and is placed outside the nucleus of the funiculus cuneatus. This is called the *accessory cuneate nucleus*, and is supposed to be a continuation upward of Clarke's vesicular column of the cord.

The Upper Part of the Medulla.—The upper part of the medulla comprises the portion which enters into the formation of the floor of the fourth ventricle, where, in fact, the upper end of the central canal has opened out into this cavity. In this region the *formatio reticularis* is confined chiefly to the anterior and lateral areas. In the ventral portion of the posterior area there is only a small amount of reticular formation, but in addition to this there are individual masses of cells scattered among the longitudinal fibres.

The *formatio reticularis* is situated in the medulla, behind the pyramid and olivary body, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the floor of the fourth ventricle. It presents a peculiar reticulated appearance, from which it derives its name, and which is due to the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others transverse. The *formatio reticularis* presents a different appearance in the anterior area from what it does in the lateral area. In the former there is almost an entire absence of nerve-cells in the reticulated network, and hence it is known as the *formatio reticularis alba*; whereas, in the lateral area, the nerve-cells are numerous, and, as a consequence, this part is known as the *formatio reticularis grisea*. In the substance of the *formatio reticularis* is a small nucleus of gray matter. It is situated near the dorsal aspect of the hilum of the olivary nucleus, and has been named the *inferior central nucleus*. The fibres of the *formatio reticularis* are longitudinal and transverse. In the anterior area the longitudinal fibres may be arranged in two well-defined sets: (1) one set lies immediately behind the pyramid, and is named the *fillet* or *lemniscus*. The fibres of the fillet are chiefly derived from the cells of the gracile and cuneate nuclei, and may therefore be regarded as relay fibres of the columns of Goll and Burdach of the spinal cord, which terminate in synapses around the cells of the gracile and cuneate nuclei. They are prolonged inward and forward across the middle line forming the superior pyramidal or sensory decussation (decussation of the fillet); (2) the other set is continued from the antero-lateral ground bundle of the cord, and a portion of these fibres forms the *posterior longitudinal bundle* already referred to (page 695). Both these sets of fibres are continued upward into the pons and mid-brain. The longitudinal fibres of the reticular formation in the lateral area are not arranged in distinct bundles. They are derived from the lateral column of the cord, after the crossed pyramidal tract has passed over to the opposite side. The longitudinal fibres of the posterior area are merely indeterminate fibres of the *formatio reticularis*, with the exception of two distinct bundles, which may be regarded as ascending roots of the fifth and vago-glosso-pharyngeal nerves; the latter is termed the *funiculus solitarius*.

The *transverse* fibres of the reticular formation are the arched or arcuate fibres. The *external arciform fibres* have already been described. The *internal arciform fibres* are more numerous than the superficial set; they traverse nearly the whole area of the upper half of the medulla, except the pyramid. They pass from the

raphé; some become superficial and join the external arciform fibres, while others remain deep and pass to the olivary body, the restiform body, and to the nuclei of the funiculus cuneatus and funiculus gracilis.

Independent Nuclei.—In the upper part of the medulla are several independent nuclei of gray matter, which may be divided into two sets: (1) those which are traceable from the gray matter of the spinal cord; and (2) those which are not represented in the cord. The former are the hypoglossal nucleus, the nucleus of the funiculus teres, and those of the auditory, glosso-pharyngeal, vagus, and spinal accessory nerves. The latter are the nucleus of the olivary body and the accessory olivary nuclei. In addition to these, small collections of gray matter are to be found in the median septum or raphé.

The Hypoglossal Nucleus.—The base of the anterior horn, which in the lower part of the medulla was situated on the ventro-lateral aspect of the central canal, now approaches the floor of the ventricle, where it lies close to the median sulcus under the funiculus teres. In it is a column of large nerve-cells, from which the roots of the hypoglossal nerve are derived. It is accordingly designated the *hypoglossal nucleus*.

The Auditory Nuclei.—Toward the upper part of the medulla, a considerable tract of gray matter may be found lying immediately beneath that portion of the floor of the fourth ventricle which is known as the trigonum acustici. This is the *dorsal* or *inner auditory nucleus*, and it lies just external to the vago-glosso-pharyngeal nucleus. In addition to this, there is a small collection of nerve-cells on the ventral surface of the restiform body, between the two roots of the auditory nerve, which is known as the *accessory* or *ventral auditory nucleus*. On the outer side of the restiform body is a mass of cells associated with the cochlear root of the auditory nerve. This mass is termed the *lateral acoustic tubercle* or *ganglion radialis cochlearis*.

Nuclei of the Glosso-pharyngeal and Vagus Nerves.—These are two in number, *principal* and *accessory*. The *principal* nucleus of the two nerves lies beneath that portion of the floor of the fourth ventricle, which is known as the ala cinerea and fovea inferior. They form an oblong mass of gray matter, above the nucleus of the spinal accessory and lateral to the hypoglossal nucleus. The *accessory* nuclei are situated in the reticular formation of the posterior area, some distance from the floor of the fourth ventricle. They consist of a pear-shaped mass of cells, which is connected with the rest of the gray matter by a sort of stalk or peduncle, and was formerly known as the *nucleus ambiguus*.

Nucleus of the Spinal Accessory Nerve.—This nucleus consists of a group of cells, which is situated partly in the lower part of the medulla at the base of the posterior horn and close to the central canal. It extends upward, lying beneath the lower part of the floor of the fourth ventricle and on the outer side of the hypoglossal nucleus.

The Nucleus of the Olivary Body.—When the olivary body is cut across, it is seen to be covered externally by white fibres, and internally to consist of a gray layer. This gray layer is the *nucleus of the olivary body*, or, as it is sometimes called, the *corpus dentatum of the olive*. It is composed of a thin, wavy lamina, which is arranged in the form of a hollow capsule, open at its upper and inner part, and presenting a zigzag or dentated outline. Microscopically examined, the olivary nucleus is seen to consist of small rounded yellowish nerve-cells embedded in a matrix of neuroglia and fine nerve-fibres. White fibres, which can be traced from the raphé, and are probably derived from the opposite olive, enter the interior of the capsule by the aperture at its upper or inner part, constituting the olivary peduncle.

The fibres of the olivary peduncle as they enter the body diverge, and some are lost in the gray matter of the olivary nucleus; others pass through it, and of these some turn backward to join the restiform body, and pass to the cerebellum as internal arcuate fibres; while others pierce the white matter of the olivary body and, reaching the surface, are continued to the restiform body as external arcuate

fibres. The fibres of the olivary peduncle connect the olivary nucleus with the cerebral hemisphere of the same side. The nucleus is also connected to the anterior horn of the same side of the cord; and with the opposite cerebellar hemisphere through the internal arcuate fibres. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

Accessory Olivary Nuclei.—Two small isolated masses of gray matter are to be found, one on the mesial and the other on the dorsal aspect of the corpus dentatum. These are the *mesial* and *lateral accessory olivary nuclei*. They are connected with the restiform body by some of the internal arcuate fibres. The fibres of the hypoglossal nerve, as they traverse the bulb, pass between the mesial accessory nucleus and the chief olivary nucleus.

The Raphe.—The *raphé* is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions, which can only be seen in suitable microscopic sections, thus: 1. Some are antero-posterior; these in front are continuous with the superficial arciform fibres. 2. Some are longitudinal; these are derived from the arciform fibres, which on entering the *raphé* change their direction and become longitudinal. 3. Some are oblique; these are continuous with the deep arciform fibres which pass from the *raphé*.

The nerve-cells of the *raphé* are multipolar; some are connected with the antero-posterior fibres, others with the superficial arcuate fibres.

Fig. 373.—Side view of the brain of man, showing the localization of various functions. (After Ferrier.) 1. Centre for movements of opposite leg and foot. 2, 3, 4. Centres for complex movements of the arms and legs, as in swimming. 5. Extension forward of the arm and hand. 6. Supination of the hand and flexion of the forearm. 7, 8. Elevators and depressors of the angle of the mouth. 9, 10. Movements of the lips and tongue. 11. Retraction of the angle of the mouth. 12. Movements of the eyes. 13, 13'. Vision. 14. Hearing. a, b, c, d. Movements of the wrists and fingers.

Weight of the Encephalon.—The average weight of the brain in the adult male is $49\frac{1}{2}$ oz., or a little more than 3 lbs. avoirdupois; that of the female 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain in the male ranges between 46 oz. and 53 oz., and in the female between 41 oz. and 47 oz. In the male the maximum weight out of 278 cases was 65 oz., and the minimum weight 34 oz. The maximum weight of the adult female

brain, out of 191 cases, was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man's brain is 1424 grammes (about 45 oz.), of a woman's 1272 grammes (about 41 oz.), and, according to Krause, 1570 grammes (about 48½ oz.) for the male, and 1350 (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes.

FIG. 374.—Top view of the brain of man, showing the localization of various functions. (After Ferrier.)
 1. Centre for movements of opposite leg and foot. 2, 3, 4. Centres for complex movements of the arms and legs, as in swimming. 5. Extension forward of the arm and hand. 6. Supination of the hand and flexion of the forearm. 7, 8. Elevators and depressors of the angle of the mouth. 9, 10. Movements of the lips and tongue. 11. Retraction of the angle of the mouth. 12. Movements of the eyes. 13, 13'. Vision. 14. Hearing. a, b, c, d. Movements of the wrists and fingers.

The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier's brain weighed rather more than 64 oz., that of the late Dr. Abercrombie 63 oz., and that of Dupuytren 62½ oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldennan of Cincinnati has recorded the case of a mulatto, aged forty-five, whose brain weighed 68½ oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. M. Nikiforoff

has published an article on the subject of the weight of brains in the *Novosti*. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. It is equally important to know what was the cause of death, for long illness or old age exhausts the brain. To define the real degree of development of the brain it is therefore necessary to have a knowledge of the condition of the whole body, and, as this is usually lacking, the mere record of weight possesses little significance.

The human brain is heavier than that of all the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

FIG. 375.—Drawing to illustrate cranio-cerebral topography. (Taken from a cast in the Museum of the Royal College of Surgeons of England, prepared by Professor Cunningham.)

Cerebral Localization and Topography.—Physiological and pathological research have now gone far to prove that the surface of the brain may be mapped out into series of definite areas, each one of which is intimately connected with some well-defined function. And this is especially true with regard to the convolutions on either side of the fissure of Rolando, which are believed by most physiologists of the present day to be concerned in motion, those grouped around the fissure being associated with movements of the extremities of the opposite side of the body, and those around the lower end of the fissure being related to movements of the mouth and tongue.

This is not the place, nor can space be given, to describe these localities. But the two accompanying cuts from Ferrier (Figs. 373, 374) have been introduced, and will serve to indicate the position of the more important areas.

The relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp has been the subject of much investigation, and many systems have been

devised by which one may localize these parts from an examination of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area.

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 222), and the relation of the fissures and convolutions to these landmarks is as follows:

Longitudinal Fissure.—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

The Fissure of Sylvius.—The position of the fissure of Sylvius and its horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is, therefore, two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

Fissure of Rolando.—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the sulcus will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method, but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for $3\frac{1}{4}$

FIG. 376.—Relations of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp. (Reid.)

inches, its axis making an angle of 67° with the middle line. Cunningham states that this angle more nearly averages 71.5° . In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction

and $3\frac{1}{4}$ inches will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrtometer, which combines the scale of measurements for localizing the fissure with data for representing its length and direction.¹ Professor Thane gives the lower end of the furrow as "close to the posterior limb, and about half an inch behind the bifurcation of the fissure of Sylvius." So that, according to this anatomist, a line drawn from a point half an inch behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the fissure of Rolando. Dr. Reid adopts a different method (Fig. 376). He first indicates on the surface the longitudinal fissure and the horizontal limb of the fissure of Sylvius (as above). He then draws two perpendicular lines from his "base-line" (that is, a line from the lowest part of the infra-orbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (D E, Fig. 376) from the depression in front of the external auditory meatus, and the other (F G, Fig. 376) from the posterior border of the mastoid process at its root. He has thus described on the surface of the head a four-sided figure (F D G E, Fig. 376), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the fissure of Sylvius will represent the furrow.

The *parieto-occipital fissure* on the upper surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about an inch, from a point one-fifth of an inch in front of the lambda (posterior fontanelle). Reid states that if the horizontal limb of the fissure of Sylvius be continued onward to the sagittal suture, the last inch of this line will indicate the position of the sulcus.

The *precentral sulcus* begins four-fifths of an inch in front of the middle of the fissure of Rolando, and extends nearly, but not quite, to the horizontal limb of the fissure of Sylvius.

The *superior frontal fissure* runs backward from the supra-orbital notch, parallel with the line of the longitudinal fissure to two-fifths of an inch in front of the line indicating the position of the fissure of Rolando.

The *inferior frontal fissure* follows the course of the superior temporal ridge on the frontal bone.

The *intraparietal fissure* begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the posterior fontanelle and the parietal eminence.

THE SPINAL CORD AND ITS MEMBRANES.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the spinal canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawn through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps.

MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the *dura mater*, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the *pia mater*, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the *arachnoid membrane*, a non-vascular membrane which envelops the cord and is connected to the pia mater by slender filaments of connective tissue.

The **Dura Mater** of the cord represents only the meningeal or supporting layer of the cranial dura mater. The endocranial or endosteal layer ceases at the foramen magnum posteriorly, but reaches as low as the third cervical vertebra in front; below these levels its place is taken by the periosteum. It forms a loose sheath which surrounds the cord, and is separated from the bony walls of the spinal canal by a quantity of loose areolar tissue and a plexus of veins. The situation of the veins between the dura mater of the cord and the periosteum of the vertebrae corresponds therefore to that of the cranial sinuses between the endocranial and supporting layers. It is attached to the circumference of the foramen magnum, and to the axis and third cervical vertebra; it is also fixed to the posterior common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the second or third piece of the sacrum; here it becomes

¹ *Lancet*, 1888, vol. i., p. 408.

impervious, and, ensheathing the flum terminale, descends to the back of the coccyx, where it blends with the periosteum. The dura mater is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura mater are short in the upper part of the spine, but become gradually longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the spinal canal.

The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:

The dura mater of the cord is not adherent to the bones of the spinal canal, which have an independent periosteum.

It does not send partitions into the fissures of the cord, as in the brain.

Its fibrous laminae do not separate to form venous sinuses, as in the brain.

Structure.—The dura mater consists of white fibrous and elastic tissue arranged in bands or lamellæ, which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is covered by a layer of endothelial cells which gives this surface its smooth appearance. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The **Arachnoid** is exposed by slitting up the dura mater and reflecting that membrane to either side (Fig. 377). It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid, on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, joined together by isolated connective-tissue trabeculæ, especially on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the *subdural space*. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the *subarachnoid space*. The space is the largest at the lower part of the spinal canal, and

FIG. 377.—The spinal cord and its membranes.

encloses the mass of nerves which form the cauda equina. Superiorly it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of an opening in the pia mater, in the roof of the fourth ventricle (*foramen of Majendie* and *foramina of Key and Retzius*). It contains an abundant serous secretion, the *cerebro-spinal fluid*. This secretion is sufficient in amount to expand the arachnoid membrane, so as to fill up completely the whole of the space included in the dura mater. The subarachnoid space is occupied by trabeculæ of delicate connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named *subarachnoid tissue*. In addition to this it is partially subdivided by a longitudinal membranous partition, the *septum posticum*, which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure of the spinal cord, a partition which is incomplete and cribriform in structure, consisting of bundles of white fibrous tissue interlacing with each other. This space is to be regarded as, in reality, a great lymph space, from which the

lymph carried to it by the perivascular lymphatics is conveyed back into the circulation.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers.

The **Pia Mater** of the cord is exposed on the removal of the arachnoid (Fig. 377). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the *linea splendens*; and a somewhat similar band, the *ligamentum denticulatum*, is situated on each side. At the point where the cord terminates the pia mater becomes contracted, and is continued down as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina. It perforates the dura about the level of the second or third lumbar vertebræ, receiving a sheath from it, and extends downward as far as the base of the coccyx, where it blends with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk, and is from this circumstance called the *central ligament* of the spinal cord. It contains a little gray nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia mater presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

Structure.—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner, consisting of stiff bundles of the same tissue, which present peculiar angular bends, and is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleftlike lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. It is also supplied with nerves, which are derived from the sympathetic.

The **Ligamentum Denticulatum** (Fig. 377) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura mater. These serrations are twenty-one in number on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

Surgical Anatomy.—Evidence of great value in the diagnosis of meningitis may be obtained by puncturing the theca of the cord and withdrawing some of the cerebrospinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebrospinal fluid relieves the patient by diminishing the intracranial pressure. The

FIG. 378.—Transverse section of the spinal cord and its membranes. (Gegenbaur.)

FIG. 379.—Posterior view of the spinal cord *in situ*.

operation is performed by inserting a trocar, of the smallest size, between the lamina of the third and fourth or the fourth and fifth lumbar vertebræ through the ligamenta subflava. The spinal cord even of a child at birth does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth vertebra without any risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the median line.

THE SPINAL CORD (Fig. 379).

The **Spinal Cord** (*medulla spinalis*) is the cylindrical, elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half, its proportion to the encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance, which

FIG. 380.—Spinal cord. Side view. Plan of the fissures and columns.

is continued for some distance into the *filum terminale*. In the fœtus, before the third month, it extends to the bottom of the sacral canal, but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that of the cord, so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. On examining its surface it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The cervical enlargement extends from about the third cervical to the first or second dorsal vertebra: its greatest diameter is in the transverse direction (13 mm.), and it corresponds with the origin of the nerves

which supply the upper extremities. The lumbar enlargement is situated opposite the last two or three dorsal vertebræ, and corresponds with the origin of the nerves which supply the lower extremities. Below the lumbar enlargement the cord gradually tapers to form a cone, the *conus medullaris*, the apex of which is continuous with the filum terminale. In form, the spinal cord is a cylinder, flattened before and behind.

Fissures.—It presents on its anterior surface, along the middle line, a longitudinal fissure, the *anterior median fissure*, and on its posterior surface another fissure, which also extends along the entire length of the cord, the *posterior median fissure*. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide the cord into symmetrical halves, united in the middle line by a transverse band of nervous substance, the *commissure*.

The **Anterior Median Fissure** is wider, but of less depth, than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the lower part of the cord. It contains a prolongation from the pia mater, and its floor is formed by the *anterior white commissure*, which is perforated by numerous blood-vessels passing to the centre of the cord.

The **Posterior Median Fissure** is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one-half its depth, and its floor is formed by the *posterior gray commissure*.

FIG. 381.—Transverse sections of the cord.

FIG. 382.—From a transverse section through the spinal cord of a calf. Magnified about 180 diameters, showing part of the central canal and the tissue immediately around it, viz., the central gray matter. (Klein and Noble Smith.) The canal is lined with epithelium, composed of ciliated, more or less conical, cells; in most instances a filamentous process passes from the cell into the tissue underneath. This tissue contains, in a hyaline matrix, a network of fibrils; most of these run horizontally; others have a longitudinal course, and appear therefore here cut transversely—i. e., as small dots. The nuclei correspond to the cells of the neuroglia, the cell-substance not being shown. Both the nuclei of the neuroglia-cells and those of the epithelium contain three or more large disc-shaped particles.

Lateral Fissures.—On each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the gray matter which approaches the surface in this situation; this is called the *postero-lateral fissure* of the spinal cord. On the posterior surface of the spinal cord, between the posterior median fissure and the postero-lateral fissure on each side, is a slight longitudinal furrow (*posterior intermediate furrow*), marking off two slender tracts, the *postero-median* and *postero-lateral columns*. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord. On each side of the anterior median fissure the anterior roots of the spinal nerves emerge from the cord, not in one vertical line, but by separate bundles which occupy an area of some width. This is called, by some anatomists, the *antero-lateral fissure* of the cord, although no actual fissure exists in this situation.

Columns of the Cord.—Each half of the spinal cord is thus divided into four columns: an anterior column, a lateral column, a posterior column, and a postero-median column. This division, however, is very imperfect, since the limit between

the so-called anterior and lateral columns cannot be defined on account of the bundles of the anterior roots being spread over a considerable area. It is therefore customary to divide each half of the spinal cord into two columns, separated by the postero-lateral groove: (1) a small *posterior column*, which is bounded internally by the posterior median fissure, and externally by the postero-lateral fissure, and (2) a large *antero-lateral column*, which comprises the rest of the cord. The posterior column is further divided, at all events at its upper part, by the posterior intermediate septum, into a postero-median column and a postero-lateral column.

Structure of the Cord.—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nervous substance. The white matter is situated externally, and constitutes the greater part. The gray substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a transverse band of gray matter, the *gray commissure*. Each crescentic mass has an anterior (ventral) and a posterior (dorsal) horn. The posterior horn is long and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the *caput cornu*: from this it tapers to form the *apex cornu*, which at the surface of the cord becomes continuous with some of the fibres of the posterior roots of the spinal nerves. The anterior horn is short and thick, and does not quite reach the surface, but extends toward the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. Owing to the projections toward the surface of the anterior and posterior horns of the gray matter, each half of the cord is divided, more or less completely, into three columns, anterior, middle, and posterior, the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

The *commissure of the spinal cord* is composed of white and gray matter, and is therefore divided into the white and gray commissures. The *white commissure* is situated at the bottom of the anterior median fissure, and is formed of medullated nerve-fibres, which pass between the gray matter of the anterior horn and the anterior white column of the one side into similar parts on the other. The fibres are oblique in direction; many which enter at the posterior part of the commissure on the one side leave it at the anterior part of the commissure on the other, and *vice versa*, a decussation taking place in the middle line.

The *gray commissure*, which connects the two crescentic masses of gray matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse medullated nerve-fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge: some pass backward to the posterior roots; others spread out, at various angles, into the crescent.

Running through the gray commissure of the whole length of the cord is a minute canal, which is barely visible to the naked eye in the human cord, but is proportionately larger in some of the lower vertebrata. It is called the *central canal*; it opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity. It is surrounded by an area of neuroglia, which, in the recent state, has a gelatinous appearance, and in which there are no nerve-fibres. This is sometimes called the *substantia gelatinosa centralis*. When hardened in alcohol or chromic salts it has a finely reticulated appearance. The canal is lined in the foetus by columnar ciliated epithelium, but in the adult the cilia have disappeared, and the canal is filled with their remains.

The mode of arrangement of the gray matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the dorsal; short, but wider, in the lumbar region. In the cervical region the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region the gray matter is least developed, the white matter being also small in quantity. In the lumbar region the gray matter is more abundant

than in any other region of the cord. Toward the lower end of the cord the white matter gradually ceases. The crescentic portions of the gray matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the *white substance*; and of a central part, the *gray matter*, both supported in a peculiar kind of tissue, called *neuroglia*.

The *neuroglia* consists of a homogeneous transparent matrix, of a network of very delicate fibrillæ, and of small stellate or branched cells, the *neuroglia-cells*.

In addition to forming a ground substance, in which the nerve-fibres, nerve-cells, and blood-vessels are imbedded, a considerable accumulation of neuroglia takes place in three situations—(1) on the surface of the cord, beneath the pia mater; (2) around the central canal, the *substantia gelatinosa centralis*; and (3) as a cap over the extremity of the posterior horn, forming the *substantia cinerea gelatinosa*.

The *white substance of the cord* consists of medullated nerve-fibres, mostly disposed longitudinally, with blood-vessels and neuroglia. When stained with carmine it presents a very striking appearance on transverse section. It is seen to be studded all over with minute dots, surrounded by a white area (Fig. 387). This is due to the longitudinal medullated fibres seen on section. The dot is the axis-cylinder, the white area the substance of Schwann. Externally, the neuroglia forms a sheath closely investing the outer surface of the cord immediately beneath the pia mater; from it numerous septa pass inward and separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium, in which they are imbedded.

There are, however, also oblique and transverse fibres in the white substance. These principally consist of (1) the fibres of the white commissure (2) horizontal or oblique fibres passing from the roots of the nerves into the gray matter; and (3) fibres leaving the gray matter and pursuing a longer or shorter horizontal course.

Conducting Tracts.—It is impossible to trace the course of the nerve-fibres in their passage through the cord; but the investigation of pathological lesions has shown that the white matter of the cord consists of certain columns or tracts of fibres; for it has been found that certain lesions are strictly limited to certain well-determined parts of the cord without involving neighboring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special functions, seems abundantly proved by the researches of Flechsig and others on the development of the spinal cord during the later periods of utero-gestation and in the newly born infant. By these researches several tracts can be traced along the greater part of the cord and into or from the encephalon. Thus (1) in the antero-lateral column of the cord, on either side of the anterior median fissure, a portion of the column may be divided off as the *direct pyramidal tract* (*fasciculus of Türck*). This tract

FIG. 383.—Columns of the cord.

is only found in the upper part of the cord; it gradually diminishes as it is traced downward, and disappears about the middle of the dorsal region. It consists of centrifugal or descending fibres which can be traced downward from the pyramid of the medulla of the same side, and are derived from the motor area of the cerebral cortex. The fibres of this tract decussate in their course down the cord, passing across the middle line through the anterior white commissure; this explains the gradual diminution and eventual disappearance of the tract. (2) In the hinder part of the antero-lateral column is a somewhat triangular area, larger than the preceding, which is named the *crossed pyramidal tract*. This also consists of descending fibres, which are derived from the pyramid of the medulla of the opposite side, and which have crossed in the decussation of the pyramids. The fibres are derived from the motor area of the cerebral cortex of the opposite side. Thus it will be seen that all the fibres from the motor area, which descend through the internal capsule, the crus cerebri, and the pons Varolii to the pyramidal body of the medulla, decussate; some at the upper part of the cord, and these descend through it as the crossed pyramidal tract; and others, which descend as the direct pyramidal tract and cross through the anterior commissure of the cord to reach the crossed pyramidal tract of the opposite side. Although this is the usual method of describing the crossing of the direct pyramidal tract in the cord, it seems probable that its fibres cross in the anterior commissure and pass directly to the anterior horn of gray matter, to end by forming synapses around its cells. (3) The *antero-lateral ascending tract* (Gower's tract) is an extensive crescent-shaped strand which skirts the circumference of the anterior three-quarters of the antero-lateral column of the cord. Behind, where it is thickest, it lies in the angle formed by the direct cerebellar and crossed pyramidal tracts, becoming narrower as it passes forward toward the direct pyramidal tract. It consists of centripetal or ascending fibres, which arise from cells situated at the base of the posterior horn and which cross to the opposite side of the

cord in the anterior gray commissure. They can be traced upward through the medulla and pons to the cerebellum, reaching the latter through its superior peduncles. If the spinal cord is divided in the cervical region, some scattered fibres in this column degenerate in a downward direction. This would seem to prove therefore that it contains some descending fibres, which are believed to be derived from the same side of the cerebellum. (4) The *direct cerebellar tract* is situated at the circumference of the cord behind the preceding and external to the crossed pyramidal tract, occupying a narrow area which extends backward as far as the postero-lateral

FIG. 384.—Transverse section of the gray substance of the spinal cord, near the middle of the dorsal region. Magnified 13 diameters.

fissure or nearly so. It commences at the level of the upper lumbar region, and increases in size as it ascends and passes through the restiform body of the medulla to the cerebellum. Its fibres are derived from the cells of the posterior vesicular column of Clarke in the gray matter of the cord. (5) Close to the point where the posterior roots enter the cord, in the antero-lateral column, is a small collection of fibres, which is known as the *tract of Lissauer*; it is formed by some of the fibres of the posterior roots which run upward in the tract for a short distance, and then enter the posterior horn of the gray matter. (6) The rest of the antero-lateral column of the spinal cord is occupied by the *antero-lateral ground bundle*. It surrounds the anterior cornu and separates the antero-lateral tract and the crossed pyramidal tract from the gray matter of the cord. It consists of (a) longitudinal

commissural fibres, which unite the groups of cells in the gray matter with one another; (b) of fibres which pass across the anterior commissure from the gray matter of the opposite side; and (c) horizontal fibres belonging to the anterior roots of the nerves, which pass through it before leaving the cord.

In the posterior column of the cord there are two tracts. They are marked off from each other by the posterior intermediate furrow on the surface of the cord. The part which has been described previously as the posterior median column pretty nearly corresponds to the one tract, the *tract of Goll*, and the remainder of the posterior column corresponds to the other, the *tract of Burdach*. (7) The *tract of Goll* increases as it ascends, and consists of long, but small, fibres derived from the posterior roots of the spinal nerves, which ascend to the medulla oblongata, where they end in the nucleus gracilis. (8) The *tract of Burdach* consists of shorter, but larger, fibres than the preceding; they are, however, derived from the same source, the posterior roots; some ascend only for a short distance in the tract and then enter the gray matter and come into close relationship with the cells of the posterior vesicular column of Clarke; others incline toward the mesial plane, and, entering Goll's column, can be traced as far as the medulla. In the cervical

FIG. 385.—Transverse section of the gray substance of the spinal cord through the middle of the lumbar enlargement. On the left side of the figure groups of large cells are seen; on the right side, the course of the fibres is shown without the cells. Magnified 13 diameters.

and upper dorsal regions there is contained in the substance of Burdach's column a small strand of fibres, called the *descending comma tract*. It presents, on transverse section, the appearance of a comma, the blunt extremity of which is directed forward. The fibres forming it probably represent in part descending portions of the dorsal nerve-roots, together with descending commissural fibres within the cord itself. A small strand of similar descending fibres is seen, in the lower part of the cord, lying in the inner part of Goll's column.

The **gray substance of the cord** occupies its central part in the shape of two crescentic horns, joined together by the gray commissure. Each of these crescents has an anterior or ventral and a posterior or dorsal cornu.

The *posterior horn* consists of a slightly narrowed portion, at its base, where it is connected with the rest of the gray substance—this is the *cervix cornu*; from this it gradually expands into the main part of the horn, the *caput cornu*; around

its extremity is a lamina or layer of gelatinous material, which covers the head like a cap, and from this it tapers almost to a point, which approaches the surface of the cord at the postero-lateral groove.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein) similar to that found around the central canal (page 713), and has been named by Rolando the *substantia cinerea gelatinosa*. It probably takes its origin from the columnar cells which line the posterior part of the embryonic spinal canal.

The *anterior horn of the gray substance* in the cervical and lumbar swellings, where it gives origin to the motor nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, a *lateral horn* is found projecting outward from the lateral region of the gray matter on a level with the gray commissure in the upper part of the dorsal region of the cord; in the cervical and lumbar regions this lateral horn blends with the anterior horn, which thus becomes broad and expanded. From the concavity of the crescent, between the anterior and posterior horns, processes of gray matter extend into the white substance, where they divide and anastomose to form a network, termed the *formatio reticularis*.

FIG. 386.—Longitudinal section of the white and gray substance of the spinal cord, through the middle of the lumbar enlargement. Magnified 14 diameters.

FIG. 387.—Transverse section through the white matter of the spinal cord of a calf. Magnified about 300 diameters. (Klein and Noble Smith.)

In the upper part are shown two isolated flattened nucleated cells of the neuroglia, under a somewhat higher power than the rest. In the bulk of the figure the nerve-fibres are seen in transverse section. They are of different sizes, and possess a laminated medullary sheath surrounding the axicylinder, which was deeply stained in the preparation, and is here represented by a black dot. The nerve-fibres are embedded in the neuroglia. Among the neuroglia are also seen two branched connective-tissue cells—neuroglia-cells.

The gray commissure contains the central canal, and is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The *gray substance of the cord* consists of—(1) nerve-fibres of variable but smaller average diameter than those of the white columns; (2) nerve-cells of various shapes and sizes, with from two to eight processes; (3) blood-vessels and connective tissue.

The *nerve-fibres* of the gray matter of the posterior horn are for the most part composed of a dense interlacement of minute fibrils, intermingled with nerves

of a larger size. This interlacement is formed partly by the axons and dendrites of the cells of the gray matter, and partly by fibres which enter the gray matter and which come from various sources.

The *nerve-cells* of the gray matter are collected into groups as seen on transverse section, but they really form columns of cells placed longitudinally; or else they are found scattered throughout the whole of the gray matter.

In the anterior horn the cells consist of two chief groups: one mesial, the more constant, near the anterior column; the other lateral, near the lateral column. A second lateral group is present in the cervical and lumbar enlargements. At the base of the posterior horn on its inner side, adjoining the gray commissure, is a group of nerve-cells, called *Clarke's posterior vesicular column*, which extends from the eighth cervical to the second lumbar nerve.

At the junction of the anterior and posterior cornu, in the outer portion of the gray matter, is a third group of cells, the *lateral cell column*; this is best seen in the dorsal region. In certain regions of the cord these cells extend in among the fibres of the white matter of the lateral column, and give rise to the lateral horn. In addition to these groups a few large scattered cells are found in the posterior horn and in the substantia gelatinosa of Rolando.

Origin of the Spinal Nerves.—The roots of the spinal nerves are attached to the surface of the cord, opposite the horns of gray matter.

The *posterior nerve-root* enters the cord in two bundles, *mesial* and *lateral*. The mesial strand consists of coarse fibres which enter the outer part of the column of Burdach. The lateral strand is sometimes divided into a middle and an external bundle. The former contains large fibres, and passes through the gelatinous substance of Rolando into the posterior horn. The external bundle consists of fine fibres which assume a longitudinal direction in Lissauer's tract. All the posterior root-fibres divide into ascending and descending branches on entering the cord, and these in their turn give off collaterals. The fibres and their collaterals terminate by forming arborescences, some around the cells in the posterior horn, and others around the cells of Clarke's column, while the long ascending branches pass up in the columns of Goll and Burdach, and end by arborizing around the cells in the gracile and cuneate nuclei. Some of the fibres, however, pass to the gray matter of the opposite horn, and others to the anterior horn of the same side of the cord.

Anterior Nerve-roots.—The majority of the fibres of the anterior nerve-roots are the continuations outward of the axons of the large or small multipolar cells in the anterior horn of gray matter. Some, however, appear to pass across in the anterior white commissure to the cells in the anterior horn of the opposite side, while others extend backward to the posterior horn and outward to the lateral column of the same side.

The Nerve-tracts.

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the course taken by its more important nerve-tracts, and of the direction in which impulses pass along them. Before doing so, however, it is necessary to refer to the methods employed in elucidating this complex subject. All nerve fibres may be regarded as outgrowths from nerve-cells, and it is found that if a nerve-fibre be cut, the portion of it which is severed from the cell undergoes degeneration and becomes atrophied. Until recent years it was believed that the cell itself showed no change under such circumstances. This, however, is not the case, for if a nerve, the sciatic for instance, be divided in an animal, and after an interval of some weeks the animal be injected with methylene-blue and killed, it will be seen, on examining sections of the lumbar region of the spinal cord, that the cells are stained imperfectly or not at all, owing to a diminution, or, it may be, an entire disappearance of the chromatin, a substance which, in a normal cell, shows marked affinity for staining reagents. Further, the body of the cell is swollen, the nucleus displaced toward the periphery, and the part of the axon still attached to the altered cell is diminished in size and some-

what atrophied. Under favorable conditions the cell is capable of reassuming its normal appearance, and the axon may commence to grow. This method of injecting methylene-blue is of great value in determining the origin of nerve-fibres from their cells. Again, stimulation of certain localized areas of the brain or of the tracts arising from them is followed by the contraction of the muscles of the body. These cortical centres of the motor tracts are situated in the convolutions adjacent to the fissure of Rolando. When the stimulus is applied to one part the muscles of the hind limb contract, while other portions control the movements of the fore limb, etc. Destruction of these parts entails loss of function, paralysis of muscles, and degeneration of the tracts below the seat of injury. During life injury and disease may give rise to symptoms resembling either the effects of stimulation or those of destruction; and after death the tracts, or the centres of the tracts, are seen to be degenerated or otherwise altered. Further, by observing the development of the nervous system during the growth of the embryo, the fact is disclosed that all axis-cylinders do not acquire a medullary sheath at one and the same time. Speaking generally, it may be said that afferent fibres become medullated before efferent, and that in the case of the latter myelination occurs earlier in the brain than in the cord. By watching the effects of these different processes the functions of a considerable part of the brain and of the nerves leading from or to it have been determined.

The Motor, Efferent, or Descending Tract.

The constituent fibres of this tract are the axis-cylinder processes of cells situated in the cortex of the convolutions around the fissure of Rolando. At first they are somewhat widely diffused, but as they descend

FIG. 388.—Dorsal roots entering cord and dividing into ascending and descending branches. (Van Gehuchten.) *a*, Stem-fibre; *b*, *b*, ascending and descending limbs of bifurcation; *c*, collateral arising from stem-fibre.

through the corona radiata they gradually approach each other and pass between the lenticular nucleus and optic thalamus in the genu and anterior two-thirds of the posterior limb of the internal capsule. Proceeding downward they next occupy the middle of the pes or crura of the crus cerebri, and enter the pons Varolii, where the transverse fibres of this body not only conceal them, but divide them up into irregular bundles. Eventually they reach the medulla, and here the motor tracts form the anterior pyramids which lie one on each side of the median fissure. The transit of the fibres from the medulla is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the *decussation of the pyramids*, and descend in the opposite side of the cord as the indirect or crossed pyramidal tract. Throughout the length of the spinal cord fibres from this column pass into the gray matter, to terminate by ramifying around the cells of the anterior horn.

The more laterally placed portion of the motor tract does not decussate in the medulla, but descends as the direct or uncrossed pyramidal tract; these fibres, however, end in the anterior gray horn of the opposite side of the spinal cord by passing across in the

anterior white commissure. Further, it must be remembered that many fibres which descend in and constitute part of the motor tract decussate before reaching the medulla, and terminate by forming synapses with the nuclei of the cranial nerves situated near the aqueduct of Sylvius, in the pons or in the medulla itself. There is considerable variation in the extent to which decussation takes place in the medulla, the commonest condition being that in which about three-fourths of the fibres decussate in the medulla and the remainder in the cord.

Other Descending Tracts.

1. From the cortex of the frontal lobe, anterior to the Rolandic area, fibres arise which descend through the anterior limb of the internal capsule and enter the crista, where they lie to the inner side of the pyramidal tract; finally they enter, and end in, the pons.

2. Descending fibres also take origin in the temporo-occipital cortex and pass through the posterior limb of the internal capsule behind the fibres from the Rolandic area. They pass through the crista, where they lie to the outer side of the same tract, and end in the pons.

3. A small tract arises from the cells of the caudate nucleus and descends to end in the substantia nigra or pons. In the crus cerebri it lies immediately above the motor tract, which is on its ventral aspect.

The Sensory, Afferent, Ascending Tract.

The course taken by those fibres of the posterior nerve-roots which ascend has been arrived at by dividing the nerve-roots between their ganglia and their entrance into the spinal cord and subsequently examining the degenerated areas. It has been found that the fibres pursue an oblique course, being situated at first in the outer part of Burdach's column; higher up they occupy the middle of this column, being displaced inward by the accession of other entering fibres, while still higher they enter and are continued upward in the column of Goll. The upper cervical fibres do not reach the column of Goll, but are entirely confined to that of Burdach. The degeneration method proves that the localization of these fibres is very precise: the sacral nerves lying to the inner side of Goll's column and near its periphery; the lumbar nerves to their outer side; the dorsal nerves still more laterally: while the cervical nerves are confined to the outer part of Burdach's column.

On reaching the medulla these ascending fibres end by arborizing around the cells in the gracile and cuneate nuclei, and the further upward course of the tract is effected by the axis-cylinder processes of these cells. These new fibres decussate in the medulla, dorsal to the crossing of the motor tract, in what is termed the *superior pyramidal decussation*, the *sensory decussation*, or *decussation of the fillet*; terms which are synonymous. Having crossed the middle line they ascend through the pons and tegmentum of the crus cerebri, and, reaching the ventral surface of the optic thalamus, the majority end either in the subthalamic region or in the optic thalamus, but a small proportion is continued directly into the brain cortex. From the gray matter of the optic thalamus the fibres of the third link in the chain arise. They pass through the internal capsule and end in the cerebral cortex: those which go to the fronto-parietal cortex being situated in the extreme front part of the anterior limb of the internal capsule, while in the hinder extremity of the posterior limb other fibres pass to their distribution in the temporal and occipital cortex.

Other Ascending Tracts.

The direct cerebellar tract begins about the level of the second lumbar vertebra, and is the continuation upward of the axis-cylinders of Clarke's column. At the upper end of the cord it passes into the restiform body and through this reaches

the cerebellum. This tract seems to lose some of its fibres in the cord, since the area of its degeneration resulting from a section of the lower part of the cord diminishes from below upward; only some of its fibres therefore pass directly to the cerebellum. On the other hand, the tract is reinforced by an accession of fibres from the cord itself, so that its transverse area is greater above than below.

The antero-lateral ascending tract of Gower arises in the cord, probably as the axis-cylinders of cells situated in the posterior horn. Passing across the middle line through the anterior gray commissure the fibres ascend in the antero-lateral column of the cord, and ultimately reach the cerebellum through its superior peduncles.¹

THE CRANIAL NERVES.

The cranial nerves arise from some part of the cerebrospinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura mater lining the base of the skull. Other names are also given to them, derived from the parts to which they are distributed or from their functions. Taken in their order, from before backward, they are as follows:

- | | |
|------------------------------|---------------------------------|
| 1st. Olfactory. | 7th. Facial (Portio dura). |
| 2d. Optic. | 8th. Auditory (Portio mollis). |
| 3d. Motor oculi. | 9th. Glosso-pharyngeal. |
| 4th. Trochlear (Pathetic). | 10th. Pneumogastric (or Vagus). |
| 5th. Trifacial (Trigeminus). | 11th. Spinal accessory. |
| 6th. Abducent. | 12th. Hypoglossal. |

All the cranial nerves are connected to some part of the surface of the brain. This is termed their *superficial* or *apparent origin*. But their fibres may, in all cases, be traced deeply into the substance of the brain to some special centre of gray matter, termed a *nucleus*. This is called their *deep* or *real origin*. The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

The First Nerve (Fig. 350, page 654).

The First cranial or the Olfactory nerves (*nn. olfactorii*), the special nerves of the sense of smell, are about twenty in number. They are given off from the under surface of the olfactory bulb, an oval mass of a grayish color, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity of a slender process of brain-substance, named the *olfactory tract*. The olfactory tract and bulb have already been described (page 654).

Each nerve is surrounded by a tubular prolongation from the dura mater and pia mater, the former being lost on the periosteum lining the nose, the latter in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; and an outer set, which is distributed over the superior turbinated bone, and the surface of the ethmoid in front of it. As the filaments descend, they unite in a plexiform network, and are believed by most observers to terminate by becoming continuous with the deep extremities of the olfactory cells.

The olfactory differs in structure from other nerves in being composed exclusively of non-medullated fibres. They are deficient in the white substance of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres. The olfactory centre in the cortex is not definitely known. It is generally asso-

¹ Testut describes the ascending column of Gower as joining with the fillet, and through it being carried to the cerebral cortex.

ciated with the temporal lobe, where it probably includes the gyrus hippocampi, uncus, and hippocampus major. It is further described as comprising the part of the callosal convolution which lies below the genu and rostrum of the corpus callosum, and also the posterior part of the orbital surface of the frontal lobe.

Surgical Anatomy.—In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smelling (*anosmia*), and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the sapid substances being also odorous and simultaneously exciting the sense of smell.

The Second Nerve (Fig. 389).

The **Second or Optic nerve** (*n. opticus*), the special nerve of the sense of sight, is distributed exclusively to the eyeball. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the *optic tracts*.

The *optic tract*, at its connection with the brain, is divided into two bands, external and internal. The *external* band is the larger; it arises from the external geniculate body and from the under part of the pulvinar of the optic thalamus, and is partly continuous with the brachium of the anterior or upper quadrigeminal body. The *internal* band curves round the crusta, and passes beneath the internal geniculate body, with which it is connected, and then appears to lose itself in the brachium of the posterior or inferior quadrigeminal body. The fibres by which it is connected to the internal geniculate body are merely commissural, forming part of Gudden's commissure. From this origin the tract winds obliquely across the under surface of the crus cerebri, in the form of a flattened band, and is attached to the crus by its anterior margin. It then assumes a cylindrical form, and, as it passes forward, is connected with the tuber cinereum and lamina cinerea. It finally joins with the tract of the opposite side to form the *optic commissure*.

FIG. 389.—The left optic nerve and optic tracts.

The *commissure* or *chiasma*, somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellæ, being bounded, above, by the lamina cinerea; behind by the tuber cinereum; on either side by the anterior perforated space. Within the commissure, the optic nerves of the two sides undergo a partial decussation. The fibres which form the inner margin of each tract and posterior part of the commissure have no connection with the optic nerves. They simply pass across the commissure from one hemisphere of the brain to the other, and connect the internal geniculate bodies of the two sides. They are known as the *commissure of Gudden*. The remainder and principal part of the commissure consists of two sets of fibres, crossed and uncrossed. The *crossed*, which are the more numerous, occupy the central part of the chiasma, and pass from the optic tract of one side to the optic nerve of the other, decussating in the commissure with similar fibres of the opposite tract. The uncrossed fibres occupy the outer part of the chiasma, and pass from the tract of one side to the nerve of the same side.¹

FIG. 390.—Course of the fibres in the optic commissure.

¹ A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. See also Henle, *Nervenlehre*, p. 393, ed. 2.

The great majority of the fibres of the optic nerve consist of the afferent axons of nerve-cells in the retina. Some few, however, are efferent fibres, and grow out from the brain. The afferent fibres end in arborizations around the cells in the external geniculate body, pulvinar, and upper quadrigeminal body, which are sometimes termed the *lower visual centres*. From these nuclei other fibres are prolonged to the *cortical visual centre*, which, according to most observers, is situated in the cuneus, and probably also in the lingual lobule of the occipital lobe.

It should be stated that some fibres are detached from the optic tract, and pass through the crus cerebri to the nucleus of the third nerve. These fibres are small, and may be regarded as afferent branches for the sphincter pupillæ and ciliary muscles. Other fibres pass to the cerebellum through its superior peduncles, while others, again, are lost in the pons.

The *optic nerves* arise from the fore part of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the pia mater and arachnoid. As each nerve passes through the corresponding optic foramen it receives a sheath from the dura mater; and as it enters the orbit this sheath subdivides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve and surrounds it as far as the sclerotic. The nerve passes forward and outward through the cavity of the orbit, pierces the sclerotic and choroid coats at the back part of the eyeball, about one-eighth of an inch to the nasal side of its centre, and expands into the retina. A small artery, the *arteria centralis retinæ*, perforates the optic nerve a little behind the globe, and runs along its interior in a tubular canal of fibrous tissue. It supplies the inner surface of the retina, and is accompanied by corresponding veins.

Surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of development and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebrospinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the *arteria centralis retinæ* into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinæ.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

The Third Nerve (Figs. 391, 392, 393).

The **Third** or **Motor oculi nerve** (*n. oculo-motorius*) supplies all the muscles of the orbit except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris

orbit through the sphenoidal fissure, between the two heads of the External rectus muscle. On passing through the fissure, the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve.

The *superior division*, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebræ.

The *inferior division*, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch is given off to the lower part of the lenticular ganglion, which forms its inferior root. It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Surgical Anatomy.—Paralysis of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones entering into the formation of the sphenoidal fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the sphincter pupillæ, the ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the ciliary muscle, or myosis, contraction of the pupil, from irritation of the sphincter of the pupil.

The Fourth Nerve (Fig. 391).

The Fourth or Trochlear nerve (*n. trochlearis*), the smallest of the cranial nerves, supplies the Superior oblique muscle.

Its *apparent origin*, at the base of the brain, is on the outer side of the crus cerebri, just in front of the pons Varolii, but the fibres can be traced backward

FIG. 392.—Plan of the motor oculi nerve. (After Flower.)

behind the corpora quadrigemina to the valve of Vieussens, on the upper surface of which the two nerves decussate. Its *deep origin* may be traced to a nucleus in the floor of the aqueduct of Sylvius immediately below that of the third nerve, with which it is continuous.

Emerging from the upper end of the valve of Vieussens, the nerve is directed outward across the superior peduncle of the cerebellum, and then winds forward round the outer side of the crus cerebri, immediately above the pons Varolii, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth. It crosses the third nerve and enters the orbit through the sphenoidal fissure. It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward, above the origin of the Levator palpebræ, and finally enters the orbital surface of the Superior oblique muscle. In the outer wall of the cavernous sinus this nerve is not infrequently blended with the ophthalmic division of the fifth.

Branches of Communication.—In the outer wall of the cavernous sinus it receives some filaments from the cavernous plexus of the sympathetic. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve.

Branches of Distribution.—It gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Surgical Anatomy.—The fourth nerve when paralyzed causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing diplopia or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

The Fifth Nerve.

The **Fifth or Trifacial Nerve** (*n. trigeminus*) is the largest cranial nerve. It resembles a spinal nerve (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions are entirely sensory; the third division is partly sensory and partly motor. It arises by two roots: of these the anterior is the smaller, and is the motor root; the posterior, the larger and sensory. Its *superficial origin* is from the side of the pons Varolii, nearer to the upper than the lower border. The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The *deep origin* of the larger or sensory root is chiefly from a long tract in the medulla, the *lower sensory nucleus*, which is continuous below with the substantia gelatinosa of Rolando. The fibres from this nucleus form the so-called *ascending root of the fifth*; they pass upward through the pons and join with fibres from the locus cæruleus or *upper sensory nucleus*, which is situated to the outer side of the nucleus, from which the lower part of the motor root takes origin. The *deep origin* of the smaller or motor root is derived partly from a nucleus embedded in the gray matter of the upper part of the floor of the fourth ventricle and partly from a collection of nerve-cells situated at the side of the aqueduct of Sylvius, from which the fibres pass downward under the name of the *descending root of the fifth*. The real origin of the sensory root is from the Gasserian ganglion, which corresponds with the ganglion on a spinal nerve (see Development of Spinal Nerves in section on Embryology).

The two roots of the nerve pass forward below the tentorium cerebelli as it bridges over the notch on the inner part of the superior border of the petrous portion of the temporal bone: they then run between the bone and the dura mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form a large semilunar ganglion (*Gasserian*), while the motor

root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it.

The **Gasserian** or **semilunar ganglion**¹ is lodged in an osteo-fibrous space, the *cavum Meckelii*, near the apex of the petrous portion of the temporal bone. It is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the large superficial petrosal nerve lies underneath the ganglion.

Branches of Communication.—This ganglion receives, on its *inner side*, filaments from the carotid plexus of the sympathetic. *Branches of Distribution.*—It gives off minute branches to the tentorium cerebelli and the dura mater in the middle fossa of the cranium. From its *anterior border*, which is directed forward and outward, three large branches proceed—the *ophthalmic*, *superior maxillary*, and *inferior maxillary*. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Ophthalmic Nerve (Figs. 391, 393, 394).

The **Ophthalmic** (*n. ophthalmicus*), or first division of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossæ, and the integument of the eyebrow, forehead, and nose. It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about an inch in length, which passes forward along the outer wall of the cavernous sinus, below the other nerves, and just before entering the orbit, through the sphenoidal fissure, divides into three branches—*lachrymal*, *frontal*, and *nasal*.

Branches of Communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, communicates with the third and sixth nerves, and is not infrequently joined with the fourth.

Branches of Distribution.—It gives off recurrent filaments which pass between the layers of the tentorium, and then divides into

Lachrymal.

Frontal.

Nasal.

The **lachrymal** is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the fourth nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the fourth. It passes forward in a separate tube of dura mater, and enters the orbit through the narrowest part of the sphenoidal fissure. In the orbit it runs along the upper border of the External rectus muscle, with the lachrymal artery, and communicates with the temporo-malar branch of the superior maxillary. It enters the lachrymal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lachrymal nerve is occasionally absent, when its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lachrymal is substituted for it.

The **frontal** is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the sphenoidal fissure, and runs forward along the middle line, between the Levator palpebræ and the periosteum. Midway between

¹ A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasseri." Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was professor at Padua, 1545-1605. (See Hyrtl, *Lehrbuch der Anatomie*, p. 895 and p. 55.)

the apex and the base of the orbit it divides into two branches, supratrochlear and supra-orbital.

The *supratrochlear branch*, the smaller of the two, passes inward, above the pulley of the superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supra-orbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii and Occipito-frontalis muscles, and, dividing into branches which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper lid.

FIG. 393.—Nerves of the orbit and ophthalmic ganglion. Side view.

The *supra-orbital branch* passes forward through the supra-orbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and terminates in cutaneous and pericranial branches. The *cutaneous branches*, two in number, an inner and an outer, supply the integument of the cranium as far back as the occiput. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. The *pericranial branches* are distributed to the pericranium over the frontal and parietal bones.

The *Nasal nerve* is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Superior rectus and Superior oblique muscles, to the inner wall of the orbit, where it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the front of the cribriform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose, where it divides into two branches, an internal and an external. The *internal branch* supplies the mucous membrane near the fore part of the septum of the nose. The *external branch* descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior spongy bone; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The *ganglionic* is a slender branch, about half an inch in length, which usually arises from the nasal, between the two heads of the External rectus. It passes forward on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its superior or long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The *long ciliary nerves*, two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forward between it and the choroid, are distributed to the ciliary muscles, iris, and cornea.

The *infratrochlear branch* is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, lachrymal sac, and caruncula lachrymalis.

The Ophthalmic Ganglion (Figs. 391, 394).

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the *ophthalmic ganglion*; with the second division, the *spheno-palatine* or *Meckel's ganglion*; and with the third, the *otic* and *submaxillary ganglia*. All the four receive sensory filaments from the fifth, and motor and sympathetic filaments from various sources; these filaments are called the *roots of the ganglia*.

The **Ophthalmic, Lenticular, or Ciliary Ganglion** is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its dissection somewhat difficult.

Its *branches of communication, or roots*, are three, all of which enter its posterior border. One, the long or sensory root, is derived from the nasal branch of the ophthalmic and joins its superior angle. The second, the short or motor root, is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the spheno-palatine ganglion.

Its *branches of distribution* are the short ciliary nerves. These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves from the nasal. They pierce the sclerotic at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the *arteria centralis retinae*.

The Superior Maxillary Nerve (Fig. 395).

The **Superior Maxillary** (*n. maxillaris*), or second division of the fifth, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and, passing horizontally forward, it leaves the skull through the foramen rotundum, where it becomes more cylindrical in form and

firmer in texture. It then crosses the spheno-maxillary fossa, enters the orbit through the spheno-maxillary fissure, traverses the infra-orbital canal in the floor of the orbit, and appears upon the face at the infra-orbital foramen.¹ At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the spheno-maxillary fossa. 3. Those in the infra-orbital canal. 4. Those on the face.

In the cranium . . .	Meningeal.
Spheno-maxillary fossa	{ Orbital or temporo-malar.
	{ Spheno-palatine.
Infra-orbital canal .	{ Posterior superior dental.
	{ Middle superior dental.
	{ Anterior superior dental.
On the face . . .	{ Palpebral.
	{ Nasal.
	{ Labial.

The **meningeal branch** is given off directly after its origin from the Gasserian ganglion; it accompanies the middle meningeal artery and supplies the dura mater.

The **orbital or temporo-malar branch** arises in the spheno-maxillary fossa, enters the orbit by the spheno-maxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The *temporal branch* runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The *malar branch* passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek, and is named *subcutaneus malaræ*. It joins with the facial and the palpebral branches of the superior maxillary.

The **spheno-palatine branches**, two in number, descend to the spheno-palatine ganglion.

The **posterior superior dental branches** arise from the trunk of the nerve just as it is about to enter the infra-orbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek (*superior gingival branches*). They then enter the posterior dental canals on the zygomatic surface of the superior maxillary bone, and, passing from behind forward in the substance of the bone, communicate with the middle dental nerve, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The **middle superior dental branch** is given off from the superior maxillary nerve in the back part of the infra-orbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches. At its point of

¹ After it enters the infra-orbital canal, the nerve is frequently called the *infra-orbital*.

communication with the posterior branch is a slight thickening which has received the name of the *ganglion of Valentin*; and at its point of communication with the anterior branch is a second enlargement, which is called the *ganglion of Bochdalek*. Neither of these is probably a true ganglion.

The **anterior superior dental branch**, of large size, is given off from the superior maxillary nerve just before its exit from the infra-orbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve, and gives off a *nasal branch*, which passes through a minute canal into the nasal fossa, and supplies the mucous membrane of the fore part of the inferior meatus and the floor of this cavity, communicating with the nasal branches from Meckel's ganglion.

FIG. 395.—Distribution of the second and third divisions of the fifth nerve and submaxillary ganglion.

The **palpebral branches** pass upward beneath the *Orbicularis palpebrarum*. They supply the integument and conjunctiva of the lower eyelid with sensation, joining at the outer angle of the orbit with the facial nerve and malar branch of the orbital.

The **nasal branches** pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The **labial branches**, the largest and most numerous, descend beneath the *Levator labii superioris*, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the *infra-orbital*.

The Spheno-palatine Ganglion (Fig. 396).

The **spheno-palatine ganglion** (*Meckel's*), the largest of the cranial ganglia, is deeply placed in the spheno-maxillary fossa, close to the spheno-palatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

Its Branches of Communication.—Like the other ganglia of the fifth nerve, it possesses a motor, a sensory, and a sympathetic root. Its *sensory root* is derived from the superior maxillary nerve through its two spheno-palatine branches. These branches of the nerve, given off in the spheno-maxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its *motor root* is derived from the facial nerve through the large superficial petrosal nerve, and its *sympathetic root* from the carotid plexus, through the large deep petrosal nerve. These two nerves join together to form a single nerve, the *Vidian*, before their entrance into the ganglion.

FIG. 396.—The sphenopalatine ganglion and its branches.

The *large superficial petrosal branch* (*nervus petrosus superficialis major*) is given off from the geniculate ganglion of the facial nerve in the aqueductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward contained in a groove on the anterior surface of the petrous portion of the temporal bone, lying beneath the dura mater. It then enters the cartilaginous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the Vidian nerve.

The *large deep petrosal branch* (*nervus petrosus profundus*) is given off from the carotid plexus, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the cartilaginous substance which fills in the foramen lacerum medium, and joins with the large superficial petrosal nerve to form the Vidian.

The *Vidian nerve*, formed in the cartilaginous substance which fills in the middle lacerated foramen by the junction of the two preceding nerves, passes

forward, through the Vidian canal, with the artery of the same name, and is joined by a small ascending branch, the *sphenoidal branch*, from the otic ganglion. Finally, it enters the sphenomaxillary fossa, and joins the posterior angle of Meckel's ganglion.

Its *branches of distribution* are divisible into four groups: *ascending*, which pass to the orbit; *descending*, to the palate; *internal*, to the nose; and *posterior branches*, to the pharynx and nasal fossæ.

The *ascending branches* are two or three delicate filaments, which enter the orbit by the sphenomaxillary fissure, and supply the periosteum. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bones to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The *descending or palatine branches* are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the sphenopalatine branches of the superior maxillary nerve, and are three in number—*anterior*, *middle*, and *posterior*.

The *anterior or large palatine nerve* descends through the posterior palatine canal, emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the nasopalatine nerve. While in the posterior palatine canal it gives off *inferior nasal branches*, which enter the nose through openings in the palate bone, and ramify over the inferior turbinated bone and middle and inferior meatuses; and at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The *middle or external palatine nerve* descends through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The *posterior or small palatine nerve* descends with a minute artery through the small posterior palatine canal, emerging by a separate opening behind the posterior palatine foramen. It supplies the Levator palati and Azygos uvulæ muscles,¹ the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glossopharyngeal to form the plexus around the tonsil (*circulus tonsillaris*).

The *internal branches* are distributed to the septum and outer wall of the nasal fossæ. They are the superior nasal (*anterior*) and the nasopalatine.

The *superior nasal branches (anterior)*, four or five in number, enter the back part of the nasal fossa by the sphenopalatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum.

The *nasopalatine nerve (Cotunniius)* also enters the nasal fossa through the sphenopalatine foramen, and passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal. The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the foramina of Scarpa, the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The nasopalatine nerve furnishes a few small filaments to the mucous membrane of the septum.

The *posterior branches* are the pharyngeal (pterygo-palatine) and the upper posterior nasal branches.

The *pharyngeal nerve (pterygo-palatine)* is a small branch arising from the

¹ It is probable that this is not the true motor supply to these muscles, but that they are supplied by the spinal accessory through the pharyngeal plexus.

back part of the ganglion, being generally blended with the Vidian nerve. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The *upper posterior nasal branches* are a few twigs given off from the posterior part of the ganglion, which run backward in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

The Inferior Maxillary Nerve (Fig. 395).

The **Inferior Maxillary Nerve** (*n. mandibularis*) distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the fifth, and is made up of two roots: a large or sensory root proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion, and unites with the sensory root just after its exit from the skull through the foramen ovale. Immediately beneath the base of the skull this nerve divides into two trunks, anterior and posterior. Previous to its division the primary trunk gives off from its inner side a recurrent (meningeal) branch and the nerve to the Internal pterygoid muscle.

The **recurrent branch** is given off directly after its exit from the foramen ovale. It passes backward into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater. The posterior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The **Internal Pterygoid Nerve**, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The *anterior* and smaller division, which receives nearly the whole of the motor root, divides into branches which supply the muscles of mastication. They are the masseteric, deep temporal, buccal, and external pterygoid.

The **masseteric branch** passes outward, above the External pterygoid muscle, in front of the temporo-mandibular articulation and behind the tendon of the temporal muscle; it crosses the sigmoid notch with the masseteric artery, to the deep surface of the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle, and a filament to the articulation of the jaw.

The **deep temporal branches**, two in number, anterior and posterior, supply the deep surface of the Temporal muscle. The *posterior branch*, of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The *anterior branch* is frequently given off from the buccal nerve; it is reflected upward, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Sometimes there are three deep temporal branches; the third branch (*middle deep temporal*) passes outward above the External pterygoid muscle, and runs upward on the bone to enter the deep surface of the Temporal muscle.

The **buccal branch** passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid process of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator, upon which it divides into a superior and an inferior branch. It gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The *upper branch* supplies the integument and upper part of the Buccinator muscle, joining with

the facial nerve round the facial vein. The *lower branch* passes forward to the angle of the mouth: it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.¹

The **External Pterygoid Nerve** is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the nerve. It enters the muscle on its inner surface.

The *posterior* and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual (gustatory), and inferior dental.

The auriculo-temporal nerve generally arises by two roots, between which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external ear and condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two temporal branches.

The *branches of communication* are with the facial and with the otic ganglion. The branches of communication with the facial, usually two in number, pass forward from behind the neck of the condyle of the jaw, to join this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The *branches of distribution* are—

Anterior auricular.

Articular.

Branches to the meatus auditorius.

Parotid.

Superficial temporal.

The *anterior auricular branches* are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

Branches to the meatus auditorius, two in number, enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani.

A *branch to the temporo-mandibular articulation* is usually derived from the auriculo-temporal nerve.

The *parotid branches* supply the parotid gland.

The *superficial temporal* accompanies the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve, and the temporal branch of the temporo-malar, from the superior maxillary.

The **lingual nerve** (gustatory) supplies the papillæ and mucous membrane of the anterior two-thirds of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of this nerve, and is occasionally joined to it by a branch which may cross the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Superior constrictor and Stylo-glossus muscles, and then between the Hyo-glossus muscle and deep part of the submaxillary gland; the nerve finally runs across Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The *branches of communication* are with the facial through the chorda tympani, the inferior dental and hypoglossal nerves, and the submaxillary ganglion.

¹ There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.

The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyoglossus muscle.

The *branches of distribution* supply the mucous membrane of the mouth, the gums, the sublingual gland, the filiform and fungiform papillæ and mucous membrane of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The **Inferior Dental** is the largest of the three branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forward in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The branches of the inferior dental are, the mylo-hyoid, dental, incisive, and mental.

The *mylo-hyoid* is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric.

The *dental branches* supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth: each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The *incisive branch* is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The *mental branch* emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the otic with the trunk of the nerve, and the submaxillary with its lingual branch.

Otic Ganglion (Fig. 397).

The **Otic Ganglion** (*Arnold's*) is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, *externally*, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; *behind* it is the middle meningeal artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short, delicate filaments. From this it may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid may contain sensory fibres. It communicates with the glosso-pharyngeal and facial nerves through the small superficial petrosal nerve continued from the tympanic plexus, and through this communication it probably receives its sensory root from the glosso-pharyngeal and its motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve. This is probably a branch from the glosso-pharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland. A slender filament (*sphenoidal*) ascends from it to the Vidian nerve.

Its *branches of distribution* are a filament to the Tensor tympani and one to the Tensor palati. The former passes backward on the outer side of the Eustachian

tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived

FIG. 397.—The otic ganglion and its branches.

from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani.

The Submaxillary Ganglion (Fig. 395).

The submaxillary ganglion is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual (gustatory) nerve.

Branches of Communication.—This ganglion is connected with the lingual (gustatory) nerve by a few filaments which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of Distribution.—These are five or six in number: they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and Wharton's duct, some being lost in the submaxillary gland. The branch of communication from the lingual to the fore part of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and face on to the face: the terminal branch of the first division emerging through the supra-orbital foramen; that of the second through the infra-orbital foramen; and the third through the mental foramen. The supra-orbital foramen is situated at the junction of the internal and middle third of the supra-orbital arch. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspid teeth of the lower jaw, it will pass over the infra-orbital and mental foramina, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

Surgical Anatomy.—The fifth nerve may be affected in its entirety, or its sensory or motor root may be affected, or one of its primary main divisions. In injury to the sensory root there is anæsthesia of the half of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed by destructive inflammation of the cornea, partly from loss of trophic influence, and partly from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient. and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of neuralgia, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The supra-orbital nerve may be exposed by making an incision an inch and a half in length along the supra-orbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supra-orbital notch. The skin and Orbicularis palpebrarum having been divided, the nerve can be easily found emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it removed. The infra-orbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infra-orbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by the best results. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is then found, divided, and a piece of silk tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including, the infra-orbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the spheno-maxillary fossa exposed. The infra-orbital canal is now opened up from below by fine cutting-pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.¹ The mental branch of the inferior dental nerve has been divided at its exit from the foramen by an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the trunk of the inferior dental nerve has been resected by an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine was then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve was dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it was by traction on the end exposed in the trephine hole, drawn out entire, and cut off as high up as possible.² The inferior dental nerve has also been divided by an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Buccinator just in front of the anterior border of the ramus of the lower jaw (Stimson).

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is required, the operation is not practicable.

The Sixth Nerve (Fig. 393).

The **Sixth or Abducent Nerve** supplies the External rectus muscle.

Its *superficial origin* is by several filaments from the constricted part of the pyramid, close to the pons, or from the lower border of the pons itself, in the groove between this body and the medulla. Its *deep origin* is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia teres.

From the nucleus of the sixth nerve fibres pass through the posterior longi-

¹ Camochan, *Amer. Journ. Med. Science*, 1858, p. 136.

² Mears, *Trans. Amer. Surg. Assoc.*, vol. ii. p. 469.

tudinal bundle to the oculo-motor nucleus of the opposite side and into the third nerve, along which they are carried to the Internal rectus muscle. The External rectus of one eye and the Internal rectus of the other may therefore be said to receive their nerves from the same nucleus—a factor of great importance in connection with the conjugate movements of the eyeball, and one that may explain certain paralytic phenomena of the Recti muscles, which are often associated with lesions in the pons.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery. It enters the orbit through the sphenoidal fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the External rectus, and is distributed to that muscle on its ocular surface.

Branches of Communication.—It is joined by several filaments from the carotid and cavernous plexus, and by one from the ophthalmic nerve.

The above-mentioned nerve, as well as the third, fourth, and the ophthalmic division of the fifth, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the *cavernous sinus* (Fig. 327) the third, fourth, and ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical order both from above downward and from within outward. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth approaches the rest, so that their relative position becomes considerably changed.

In the *sphenoidal fissure* (Fig. 398) the fourth and the frontal and lachrymal divisions of the ophthalmic lie upon the same plane as the former being most

FIG. 398.—Relations of structures passing through the sphenoidal fissure.

internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus. The superior division of the third is the highest of these; beneath this lies the nasal branch of the ophthalmic; then the inferior division of the third; and the sixth lowest of all.

In the *orbit* the fourth and the frontal and lachrymal divisions of the ophthalmic lie on the same plane immediately beneath the periosteum, the fourth nerve being internal and resting on the Superior oblique, the frontal resting on the Levator palpebræ, and the lachrymal on the External rectus. Next in order comes the superior division of the third nerve, lying immediately beneath the Superior rectus, and then the nasal branch of the ophthalmic, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular

ganglion on its outer side, between it and the External rectus. Below the optic is the inferior division of the third and the sixth, which lies on the outer side of the orbit.

Surgical Anatomy.—The sixth nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

The Seventh Nerve (Figs. 399, 400, 401).

The **Seventh** or **Facial Nerve** (*portio dura*) is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the External ear; the posterior belly of the Digastric, and the Stylo-hyoid. Its chorda tympani branch is the nerve of taste for the anterior two-thirds of the tongue and the vaso-dilator nerve of the submaxillary and sublingual glands; its tympanic branch supplies the Stapedius.

Its *superficial origin* is from the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. Its *deep origin* is from a nucleus situated in the reticular formation of the lower part of the pons, a little external and ventral to the nucleus of the sixth nerve. From this origin the fibres pursue a curved course in the substance of the pons. They first pass backward and inward, and then turn upward and forward forming the funiculus teres, which produces an eminence (eminencia teres) on the floor of the

FIG. 399.—The course and connections of the facial nerve in the temporal bone.

fourth ventricle, and finally bend sharply downward and outward round the upper end of the nucleus of origin of the sixth nerve, to reach their superficial origin between the olivary and restiform bodies. From the nucleus of the third nerve some fibres arise which descend in the posterior longitudinal bundle and join the facial just before it leaves the pons; these fibres are said to supply the anterior belly of the Occipito-frontalis, Orbicularis palpebrarum, and the Corrugator supercillii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

The auditory nerve (*portio mollis*) lies to its outer side; and between the two is a small fasciculus, the *pars intermedia* of Wrisberg, which arises from the medulla and joins the facial nerve in the internal auditory meatus. The deep origin of the *pars intermedia* is from the upper end of the nucleus of the glossopharyngeal nerve, and at its emergence it is frequently connected with both nerves.

The *pars intermedia* may be regarded as the sensory root of the facial nerve, analogous to the sensory root of the fifth, and its real nucleus of origin would then consist of the geniculate ganglion.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the internal auditory meatus with the auditory nerve. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve, and the *pars intermedia* is placed between the two, and joins the inner angle of the geniculate ganglion. Occasionally a few of its fibres pass into the auditory nerve. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani.

At the bottom of the meatus, the facial nerve enters the aquæductus Fallopii, and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus, to its termination at the stylo-mastoid foramen. It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it then bends suddenly backward and arches downward behind the tympanum to the stylo-mastoid foramen.

At the point where it changes its direction, it presents a reddish gangliform swelling (*intumescencia ganglioformis*, or *geniculate ganglion*). On emerging from the stylo-mastoid foramen it runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, *temporo-facial* and *cervico-facial*, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of *pes anserinus* is given to the divisions of the facial nerve in and near the parotid gland.

The communications of the facial nerve may be thus arranged:

In the internal auditory meatus .	With the auditory nerve.
	{ With Meckel's ganglion by the large superficial petrosal nerve.
From the geniculate ganglion .	{ With the otic ganglion by the small superficial petrosal nerve.
	{ With the sympathetic on the middle meningeal by the external superficial petrosal nerve.
In the Fallopian aqueduct .	{ With the auricular branch of the pneumogastric.
	{ With the glosso-pharyngeal.
At its exit from the stylo-mastoid foramen	{ With the pneumogastric.
	{ With the auricularis magnus.
	{ With the auriculo-temporal.
Behind the ear	With the small occipital.
On the face	With the three divisions of the fifth.
In the neck	With the superficial cervical.

In the internal auditory meatus some minute filaments pass between the facial and auditory nerves.

Opposite the hiatus Fallopii, the gangliform enlargement on the facial nerve communicates with Meckel's ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylo-mastoid foramen it generally receives a twig of communication from the auricular branch of the pneumogastric.

After its exit from the stylo-mastoid foramen, it sends a twig to the glosso-pharyngeal, another to the pneumogastric nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculo-temporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital behind the ear, on the face with the terminal branches of the three divisions of the fifth, and in the neck with the transverse cervical.

BRANCHES OF DISTRIBUTION.

Within the aquæductus Fallopii .	{ Tympanic, to the Stapedius muscle.
	{ Chorda tympani.
At its exit from the stylo-mastoid foramen	{ Posterior Auricular.
	{ Digastric.
	{ Stylo-hyoid.
	{ Temporo-facial { Temporal.
	{ Malar.
	{ Infra-orbital.
On the face	{ Buccal.
	{ Cervico-facial { Supramaxillary.
	{ Inframaxillary.

The **tympanic branch** arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The **chorda tympani** is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a

FIG. 400.—Plan of the facial nerve.

distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordæ posterior*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, and over the handle of the malleus, emerging from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordæ anterior*, or *canal of Huguier*. It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is by many regarded as the continuation of the pars intermedia of Wrisberg.

The **Posterior auricular nerve** arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process, where it is joined by a filament from the auricular branch of the pneumogastric, and communicates with the mastoid branch of the great auricular and with the small occipital. As it ascends between the meatus and mastoid process it divides into two branches. The *auricular branch* supplies the Retrahens auriculum and the small muscles on the cranial surface of the pinna. The *occipital branch*, the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The **digastric** branch usually arises by a common trunk with the **Stylo-hyoid** branch: it divides into several filaments, which supply the posterior belly of the **Digastric**; one of these perforates that muscle to join the **glosso-pharyngeal** nerve.

The stylo-hyoid is a long, slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle.

The **Temporo-facial**, the larger of the two terminal branches, passes upward and forward through the parotid glands, crosses the external carotid artery and temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infra-orbital.

FIG. 401.—The nerves of the scalp, face, and side of the neck.

The *temporal branches* cross the zygoma to the temporal region, supplying the Attrahens and Attollens auriculam muscles, and join with the temporal branch of the temporo-malar, a branch of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, joining with the supra-orbital and lachrymal branches of the ophthalmic.

The *malar branches* pass across the malar bone to the outer angle of the orbit,

where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (*subcutaneus malæ*) of the superior maxillary nerve.

The *infra-orbital*, of larger size than the rest, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The *superficial branches* run beneath the skin and above the superficial muscles of the face, which they supply: some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The *deep branches* pass beneath the Zygomatici and the Levator labii superioris, supplying them and the Levator anguli oris, and form a plexus (*infra-orbital*) by joining with the infra-orbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial. This branch also supplies the Levator labii superioris alæque nasi and the small muscles of the nose.

The Cervico-facial division of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, supramaxillary, and inframaxillary.

The *buccal branches* cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infra-orbital branches of the temporo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The *supramaxillary* or *mandibular branches* pass forward beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The *inframaxillary* or *cervical branches* run forward beneath the Platysma, and form a series of arches across the side of the neck over the suprahyoid region. One of these branches descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

Surgical Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—i. e. blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in "bulbar paralysis." Or (2) it may be paralyzed in its passage through the petrous bone by damage due to middle-ear disease or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as "Bell's paralysis." It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.

When the cause is central, the sixth nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electrical reactions are the same as in health; whereas, when the paralysis is in the course of the nerve, the reaction is usually lost. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; and the sense of hearing is affected from paralysis of the Stapedius. When the cause of the paralysis is from fracture of the base of the skull, the auditory nerve and the petrosal nerves, which are connected with the intumescencia ganglioformis, are also involved. When the injury to the nerve is after its exit from the stylo-mastoid foramen, all the muscles of expression, except the Levator palpebræ, together with the posterior belly of the Digastric and Stylo-hyoid, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the naso-labial furrow; the nostril cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator.

The facial nerve is at fault in cases of so-called "histrionic spasm," which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the

Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve.

Eighth Nerve.

The **Eighth or Auditory Nerve** (*portio mollis*) is the special nerve of the sense of hearing, being distributed exclusively to the internal ear.

Origin of the Eighth Nerve.—The eighth nerve consists of two sets of fibres, which, although differing in their central connections, are both concerned in the transmission of afferent impulses from the internal ear to the medulla and pons, and from there, by means of new fibres which arise from collections of gray matter in these structures, to the cerebrum and cerebellum. One set of fibres forms the vestibular root of the nerve, and arises from the cells in the ganglion of Scarpa; the other set constitutes the cochlear root, and takes origin from the cells in the ganglion spirale or ganglion of Corti. At its connection with the brain the eighth nerve occupies the groove between the pons and medulla, where it is situated between the restiform body, which is behind, and the seventh nerve, which is in front.

Vestibular or Ventral Root.—The fibres of this root enter the medulla to the inner side of those of the cochlear root, and pass between the restiform body, which is to their outer side, and the inferior root of the fifth, which lies to their inner side. They then divide into an ascending and a descending set. The fibres of the latter end by arborizing round the cells of the internal nucleus, which is situated in the *trigonum acustici* in the floor of the fourth ventricle. The ascending fibres either end in the same manner or in the *external nucleus*, which is situated to the outer side of the *trigonum acustici* and farther from the ventricular floor. It is described as consisting of two parts, an inner, the *nucleus of Deiters*, and an outer, the *nucleus of Bechteren*. Some of the axons of the cells of the external nucleus, and possibly also of the internal nucleus, are continued upward through the restiform body to the roof nuclei of the opposite side of the cerebellum, to which also are prolonged other fibres of the vestibular root without undergoing a relay in the nuclei of the medulla. A second set of fibres from the internal and external nuclei end partly in the tegmentum, while the remainder ascend in the posterior longitudinal bundle to arborize around the nuclei of the oculo-motor nerve.

Cochlear or Dorsal Root.—This part of the nerve is placed externally to the vestibular root. Its fibres end in two nuclei, one of which, the *accessory nucleus*, lies immediately in front of the restiform body; the other, the *tuberculum acusticum*, somewhat to its outer side.

The *striæ acusticæ* or medullary *striæ* are the axons of the cells of the *tuberculum acusticum*. They pass backward and inward over the restiform body, and across the floor of the fourth ventricle toward the middle line. Here they dip into the substance of the pons, to end around the cells of the *superior olive* of the same or opposite side. There are, however, other fibres, and these are both direct and crossed, which do not arborize around the tegmental nuclei, but pass into the lateral fillet. The cells of the accessory nucleus give origin to fibres which pass transversely in the pons and constitute the trapezium. The description given as to the mode of ending of the *striæ acusticæ* is applicable to that of the trapezoid fibres, viz., around the cells of the superior olive or of the *trapezoid nucleus* (which lies ventral to the olive) of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral fillet.

If the further connections of the cochlear nerve of one side, say the left, are considered, it is found that they lie to the outer side of the main sensory tract, the fillet, and are therefore termed the *lateral fillet*. The fibres comprising the left lateral fillet arise in the superior olive or trapezoid nucleus of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are

either crossed or uncrossed, the former being the axons of the cells of the right accessory nucleus or of the cells of the right tuberculum acusticum, while the latter are derived from the same cells of the left side. In the upper part of the fillet there is a collection of nerve-cells, the *nucleus of the fillet*, around the cells of which some of the fibres arborize. and from the cells of which axons originate to continue upward the tract of the lateral fillet. The ultimate ending of the left lateral fillet is partly in the quadrigeminal bodies of the same or opposite side, while the remainder of the fibres ascend in the posterior limb of the internal capsule to reach the first and perhaps the second left temporal convolution.

The auditory nerve contains a few afferent fibres which arise in the quadrigeminal bodies, the nucleus of the lateral fillet, trapezoid nucleus, and superior olive.

The auditory nerve after leaving the medulla passes forward across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partially separated by a small artery (auditory). It then enters the internal auditory meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and then divides into its two branches, *cochlear* and *vestibular*. The auditory nerve is soft in texture (hence the name, *portio mollis*), and is destitute of neurilemma. The distribution of the auditory nerve in the internal ear will be found described along with the anatomy of that organ in a subsequent page.

Surgical Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may arise from loud explosions from dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

The Ninth Pair (Figs. 402, 403, 404).

The Ninth or **Glosso-pharyngeal Nerve** is distributed, as its name implies, to the tongue and pharynx, being the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and tonsil; and the nerve of taste to all parts of the tongue to which it is distributed.

Its *superficial origin* is by three or four filaments, closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and restiform body.

Its *deep origin* may be traced through the fasciculi of the lateral tract, to three different sources: (1) some of the fibres may be traced to a nucleus of gray matter at the lower part of the floor of the fourth ventricle beneath the inferior fovea; (2) others may be traced downward into the *funiculus solitarius*, a rounded bundle of fibres in the lower part of the medulla, commencing immediately above the decussation of the pyramids (these fibres have not been distinctly traced to cells); (3) a third set of fibres take origin from the cells of the *nucleus ambiguus*. This nucleus is situated some distance from the floor of the fourth ventricle and lies slightly internal to the inferior fovea. It gives origin to the motor branches of the glosso-pharyngeal and vagus, and to the bulbar part of the spinal accessory. The real origin of the sensory fibres of the glosso-pharyngeal must be looked for in the jugular and petrosal ganglia which are developed from the neural crest.

FIG. 402.—Origin, ganglia, and communications of the ninth, tenth, and eleventh cranial nerves.

From its superficial origin it passes outward across the flocculus, and leaves the

skull at the central part of the jugular foramen, in a separate sheath of the dura mater, external to and in front of the pneumogastric and spinal accessory nerves

(Fig. 329). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylo-pharyngeus. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-pharyngeus and Middle constrictor of the pharynx. It then passes beneath the Hyoglossus, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior, the smaller, is called the *jugular ganglion*; the inferior and larger, the *petrous ganglion*, or the *ganglion of Andersch*.

The **superior or jugular ganglion** is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.

The **inferior, or petrous, ganglion** is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the former and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

The *branches of communication* are with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one to its auricular branch, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylo-mastoid foramen.

The *branches of distribution* are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **tympanic branch** (*Jacobson's nerve*) arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory, forming the tympanic plexus. This plexus gives off (1) the greater part of the small superficial petrosal nerve; (2) a branch to join the great superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the ear.

The **carotid branches** descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric and with branches of the sympathetic.

The **pharyngeal branches** are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric and sympathetic nerves to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The **muscular branch** is distributed to the Stylo-pharyngeus.

The **tonsillar branches** supply the tonsil, forming a plexus (*circulus tonsillaris*) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The **lingual branches** are two in number: one supplies the circumvallate papillæ and the mucous membrane covering the surface of the base of the tongue; the other perforates its substance, and supplies the mucous membrane and follicular glands of the posterior half of the tongue and communicates with the lingual nerve.

The Tenth Pair (Figs. 403, 404).

The Tenth or Pneumogastric Nerve (*nervus vagus* or *par vagum*) has a more extensive distribution than any of the other cranial nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres, and the pharynx, œsophagus, stomach, and heart with motor fibres. Its *superficial origin* is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its *deep origin* may be traced through the fasciculi of the medulla to terminate in a nucleus of gray matter, the *nucleus vagi*, at the lower part of the floor of the fourth ventricle beneath the ala cinerea below and continuous with the nucleus of origin of the glosso-pharyngeal. In addition to this a few fibres pass into the funiculus solitarius, and others into the nucleus ambiguus or accessory vagal nucleus. The real origin of the sensory fibres of the vagus is to be found in the cells of the ganglia on the nerve, viz., the ganglion of the root and the ganglion of the trunk. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium. In passing through this opening the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating them from the glosso-pharyngeal, which lies in front (Fig. 329). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the *jugular ganglion*, or the *ganglion of the root of the pneumogastric*: to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarges into a second gangliform swelling, called the *ganglion inferius*, or the *ganglion of the trunk of*

FIG. 404.—Course and distribution of the ninth, tenth, and eleventh nerves.

the nerve, through which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck. Here the course of the nerve becomes different on the two sides of the body.

On the *right side* the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network (*posterior pulmonary*), from the lower part of which two cords descend upon the œsophagus, on which they divide, forming, with branches from the opposite nerve, the œsophageal plexus (*plexus gulæ*); below, these branches are collected into a single cord, which runs along the back part of the œsophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the cœliac plexus.

On the *left side* the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the *posterior pulmonary plexus*, and along the anterior surface of the œsophagus, where it unites with the nerve of the right side in forming the *plexus gulæ*, to the stomach, distributing branches over its anterior surface, some extending over the great *cul-de-sac*, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The *ganglion of the root* is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glosso-pharyngeal, with the facial nerve by means of its (the ganglion's) auricular branch, and with sympathetic by means of an ascending filament from the superior cervical ganglion.

The *ganglion of the trunk* (inferior) is a plexiform cord, cylindrical in form, of a reddish color, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting Branches.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The *branches of the pneumogastric* are—

In the jugular fossa	{ Meningeal. Auricular. Pharyngeal.
In the neck	{ Superior laryngeal. Recurrent laryngeal. Cervical cardiac.
In the thorax	{ Thoracic cardiac. Anterior pulmonary. Posterior pulmonary.
In the abdomen	{ Cœsophageal. Gastric.

The **meningeal branch** is a recurrent filament given off from the ganglion of the root in the jugular foramen. It passes backward, and is distributed to the dura mater covering the posterior fossa of the base of the skull.

The **auricular branch** (*Arnold's*) arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glossopharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial: the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The **pharyngeal branch**, the principal motor nerve of the pharynx, arises from the upper part of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory: it passes across the internal carotid artery to the upper border of the Middle constrictor, where it divides into numerous filaments which join with those from the glossopharyngeal, superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus, from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament is given off, which descends and joins the hypoglossal nerve as it winds round the occipital artery.

The **superior laryngeal** is the nerve of sensation to the larynx. It is larger than the preceding, and arises from the middle of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid, where it divides into two branches, the external and internal laryngeal.

The **external laryngeal branch**, the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The **internal laryngeal branch** descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottidean glands; while others pass backward, in the aryteno-epiglottidean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The **inferior or recurrent laryngeal**, so called from its reflected course, is the motor nerve of the larynx. It arises on the right side, in front of the subclavian artery; winds from before backward round that vessel, and ascends obliquely to the side of the trachea, behind the common carotid and behind or in front of the inferior thyroid artery. On the left side it arises in front of the arch of the aorta, and winds from before backward round the aorta at the point where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerves on both sides ascend in the groove between the trachea and œsophagus, and, passing under the lower border of the Inferior constrictor muscle, enter the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx except the Crico-thyroid. It communicates with the superior laryngeal

nerve and gives off a few filaments to the mucous membrane of the lower part of the larynx.

The recurrent laryngeal, as it winds round the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneumogastric and sympathetic. As it ascends in the neck it gives off œsophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the œsophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea: and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The *cervical cardiac branches*, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The *superior branches* are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The *inferior branches*, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes in front of the arch of the aorta and joins the superficial cardiac plexus.

The *thoracic cardiac branches*, on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inward, they terminate in the deep cardiac plexus.

The *anterior pulmonary branches*, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The *posterior pulmonary branches*, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung: they are joined by filaments from the third and fourth (sometimes also first and second) thoracic ganglia of the sympathetic, and form the *posterior pulmonary plexus*. Branches from both plexuses accompany the ramification of the air-tubes through the substance of the lungs.

The *œsophageal branches* are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *œsophageal plexus* or *plexus gule*. From this plexus branches are distributed to the back of the pericardium.

The *gastric branches* are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach, and joins the left side of the cœliac plexus and the splenic plexus. The nerve on the left side is distributed over the anterior surface of the stomach, some filaments passing across the great *cul-de-sac*, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

Surgical Anatomy.—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of this same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralyzed, we have anæsthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both these recurrent nerves are paralyzed, the vocal cords are motionless, in the so-called “cadaveric position”—that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice

is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diphtheria, when it usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by bronchocele; or by cancer of the upper part of the œsophagus, when the paralysis is often unilateral.

The Eleventh Pair (Figs. 403, 404).

The Eleventh or Spinal Accessory Nerve consists of two parts: one, the accessory part to the vagus, and the other the spinal portion.

The bulbar or accessory part is the smaller of the two. Its *superficial origin* is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its *deep origin* may be traced to a nucleus of gray matter at the back of the medulla, dorso-lateral to the hypoglossal nucleus, and extending as far down as the intermedio-lateral tract of the spinal cord. It passes outward to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; it is also connected, in the foramen, with the upper ganglion of the vagus by one or two filaments. It then passes through the foramen, and becoming again separated from the spinal portion it is continued over the surface of the ganglion of the trunk of the vagus, being adherent to its surface, and is distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric. Through the pharyngeal branch it probably supplies the muscles of the soft palate (see page 331). Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves.

The spinal portion is firm in texture. Its *superficial origin* is by several filaments from the lateral tract of the cord, as low down as the sixth cervical nerve. Its *deep origin* may be traced to the intermedio-lateral tract of the gray matter of the cord. This portion of the nerve ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outward to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen it receives one or two filaments from the accessory portion. At its exit from the jugular foramen it passes backward, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid. It pierces that muscle, and passes obliquely across the posterior triangle, to terminate in the deep surface of the Trapezius. This nerve gives several branches to the Sterno-mastoid during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the posterior triangle it joins with the second and third cervical nerves, while beneath the Trapezius it forms a sort of plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Surgical Anatomy.—In cases of spasmodic torticollis in which all palliative treatment has failed, division or excision of a portion of the spinal accessory nerve has been resorted to. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making an incision from the apex of the mastoid process, three inches in length, along the anterior border of the Sterno-mastoid muscle. The anterior border of the muscle is defined and pulled backward, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle, about two inches below the apex of the mastoid process. The other operation consists in making an incision along the posterior border of the muscle, so that the centre of the incision corresponds to the middle of this border of the muscle. The superficial structures having been divided and the border of the muscle defined, the nerve is to be sought for as it emerges from the muscle to cross the occipital triangle. When found, it is to be traced upward through the muscle, and a portion of it excised above the point where it gives off its branches to the Sterno-mastoid. In this operation one of the descending branches of the superficial cervical plexus is liable to be mistaken for the nerve.

The Twelfth Pair (Figs. 405, 406).

The **Twelfth** or **Hypoglossal Nerve** is the motor nerve of the tongue.

Its *superficial origin* is by several filaments, from ten to fifteen in number, from the groove between the pyramidal and olivary bodies of the medulla, in a continuous line with the anterior roots of the spinal nerves. Its *deep origin* can be traced to a nucleus of gray matter (*trigonum hypoglossi*) on the floor of the fourth ventricle.

The filaments of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid foramen in the occipital bone is double, these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the pneumogastric nerve; it then passes forward

FIG. 405.—Plan of the hypoglossal nerve.

between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops round the occipital artery, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It passes beneath the tendon of the Digastric, the Stylo-hyoid, and the Mylo-hyoid muscles, lying between the last-named muscle and the Hyo-glossus, and communicates at the anterior border of the Hyo-glossus with the lingual (gustatory) nerve; it is then continued forward in the fibres of the Genio-hyo-glossus muscle as far as the tip of the tongue, distributing branches to its muscular substance.

The branches of communication are—with the

Pneumogastric.
Sympathetic.

First and Second Cervical Nerves.
Lingual (gustatory).

The first mentioned takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and lower ganglion of the pneumogastric through the mass of connective tissue which here unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds round the occipital artery.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

The branches of distribution are—the

Meningeal.
Descendens hypoglossi.

Thyro-hyoid.
Muscular.

Meningeal Branches.—As the hypoglossal nerve passes through the anterior

FIG. 406.—Hypoglossal nerve, cervical plexus, and their branches.

condyloid foramen it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the base of the skull; these filaments are probably

derived from a branch which passes from the first cervical nerve to the hypoglossal nerve.

The **descendens hypoglossi** is a long slender branch, which quits the hypoglossal where it turns round the occipital artery. It consists mainly of fibres which pass to the hypoglossal from the first and second cervical nerves in the above-mentioned communication. It descends in front of or within the sheath of the carotid vessels, giving off a branch to the anterior belly of the Omo-hyoid, and then joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop, the *ansa hypoglossi*. From the convexity of this loop branches pass to supply the Sterno-hyoid, Sterno-thyroid, and the posterior belly of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest, and joins the cardiac and phrenic nerves.

The **thyro-hyoid** is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The **muscular branches** are distributed to the Stylo-glossus, Hyoglossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches pass upward into the substance of the organ to supply its intrinsic muscles.

Surgical Anatomy.—The hypoglossal nerve is an important guide in the operation of ligation of the lingual artery (see page 489). It runs forward on the Hyo-glossus just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyo-glossus.

THE SPINAL NERVES.

The **spinal nerves** are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged into the following groups, corresponding to the region of the spine through which they pass :

Cervical	8 pairs.
Dorsal	12 “
Lumbar	5 “
Sacral	5 “
Coccygeal	1 pair.

It will be observed that each group of nerves corresponds in number with the vertebræ in that region, except the cervical and coccygeal.

Each spinal nerve arises by two roots, an anterior or motor root and a posterior or sensory root, the latter being distinguished by a ganglion, termed the *spinal ganglion*.

The Roots of the Spinal Nerves.

The Anterior Roots.—The *superficial origin* is from the antero-lateral columns of the cord, corresponding to the situation of the anterior cornu of gray matter. Each root is composed of from four to eight filaments.

The *deep origin* can be traced through the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the gray substance, where their fibrils diverge in several directions: some passing inward, are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornu of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass outward, to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column.

The Posterior Roots.—The *superficial origin* is from the postero-lateral fissure of the cord. The *real origin* of these fibres is from the nerve-cells in the posterior

root ganglion, from which they can be traced into the cord in two main bundles, the course of which has already been studied (page 697).

The *anterior roots* are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles near the intervertebral foramina.

The *posterior roots* of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils pass outward toward the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has occasionally no ganglion developed upon it, and when the ganglion exists, it is often situated within the dura mater.

The Ganglia of the Spinal Nerves.

A *ganglion* is developed upon the posterior root of each of the spinal nerves. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate the dura

FIG. 407.—Diagram to show the composition of a peripheral nerve-trunk. (Böhm and Davidoff.)

mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglion upon the first and second cervical nerves forms an exception to these characters, being placed on the arches of the vertebræ over which the nerves pass. The ganglia of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, is situated at some distance from the origin of the posterior root.

DISTRIBUTION OF THE SPINAL NERVES.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed constitutes the *spinal nerve*; it passes out of the intervertebral foramen, and divides into a posterior division for the supply of the posterior part of the body, and an anterior division for the supply of the anterior part of the body, each containing fibres from both roots.

Before dividing, each spinal nerve gives off a small *recurrent* or *meningeal* branch, which is joined by a filament from the communicating branch of the sympathetic, which connects the ganglion with the anterior division. It passes inward through the intervertebral foramen and supplies the dura mater, sending branches to the bones and ligaments.

The posterior divisions of the spinal nerves are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots, in the intervertebral foramina; and, passing backward, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The first cervical, the fourth and fifth sacral, and the coccygeal, do not divide into external and internal branches.

The anterior divisions of the spinal nerves supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior divisions. Each division is connected by a slender filament with the sympathetic. In the dorsal region the anterior divisions of the spinal nerves are quite separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution.

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower than the upper part. The level of their emergence from the cord is within certain

limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina. The preceding table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebræ.

THE CERVICAL NERVES.

The roots of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule: it is smaller than the anterior root. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upward and outward; the second is horizontal; the others are directed obliquely downward and outward, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

The trunk of the first cervical nerve (*suboccipital*) leaves the spinal canal between the occipital bone and the posterior arch of the atlas; the second, between the

posterior arch of the atlas and the lamina of the axis; and the eighth (the last), between the last cervical and first dorsal vertebræ.

Each nerve, at its exit from the intervertebral foramen, divides into a posterior and an anterior division. The anterior divisions of the four upper cervical nerves form the cervical plexus. The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the brachial plexus.

FIG. 408.—Posterior divisions of the upper cervical nerves.

Posterior Divisions of the Cervical Nerves (Fig. 408).

The posterior division of the first cervical (*suboccipital*) nerve differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas, lying beneath the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posterior major, the Obliquus superior, and Obliquus inferior, and supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which

accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The *posterior division of the second cervical nerve* is three or four times greater than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and an external branch.

The *internal branch*, called, from its size and distribution, the *occipitalis major*, ascends obliquely inward between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium. It is now joined by a filament from the posterior division of the third cervical nerve, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an auricular branch to the back part of the ear and muscular branches to the Complexus. The *external branch* is often joined by the external branch of the posterior division of the third, and supplies the Splenius, Trachelo-mastoid, and Complexus.

The *posterior division of the third cervical* is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve, to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an internal and external branch. The *internal branch* passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle; the *external branch* joins with that of the posterior division of the second to supply the Splenius, Trachelo-mastoid, and Complexus.

The *third occipital nerve* arises from the internal or cutaneous branch beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the *posterior cervical plexus*.

The *posterior divisions of the fourth, fifth, sixth, seventh, and eighth cervical nerves* (Fig. 415) pass backward, and divide, behind the Intertransversales muscles, into internal and external branches. The *internal branches*, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinales, Multifidus spinæ, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld). The *external branches* supply the muscles at the side of the neck—viz. the Cervicalis ascendens, Transversalis colli, and Trachelo-mastoid.

Anterior Divisions of the Cervical Nerves.

The *anterior division of the first or suboccipital nerve* is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process

of the atlas it receives a filament from the sympathetic. It then descends in front of this process, to communicate with an ascending branch from the second cervical nerve.

Communicating filaments from the loop between this nerve and the second join the pneumogastric, the hypoglossal, and sympathetic and some branches are distributed to the Rectus lateralis and the two Anterior recti. The fibres which communicate with the hypoglossal simply pass through the latter nerve to become for the most part the descendens hypoglossi. According to Valentin, the anterior division of the suboccipital distributes filaments to the occipito-atlantal articulation and mastoid process of the temporal bone.

The **anterior division of the second cervical nerve** escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides in front of the Intertransverse muscle into an ascending branch, which joins the first cervical; and one or two descending branches, which join the third. It gives off the small occipital; a branch to assist in forming the great auricular; another to assist in forming the superficial cervical; one of the communicantes hypoglossi, and a filament to the Sterno-mastoid, which communicates in the substance of the muscle with the spinal accessory.

The **anterior division of the third cervical nerve** is double the size of the preceding. At its exit from the intervertebral foramen it passes downward and outward beneath the Sterno-mastoid, and divides into two branches. The ascending branch joins the anterior division of the second cervical; the descending branch passes down in front of the Scalenus anticus and communicates with the fourth. It gives off the larger part of the great auricular and superficial cervical nerves; one of the communicantes hypoglossi; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the Levator anguli scapulæ and Trapezius; this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the Scalenus medius is derived from this source.

The **anterior division of the fourth cervical** is of the same size as the preceding. It receives a branch from the third, sends a communicating branch to the fifth cervical, and, passing downward and outward, divides into numerous filaments, which cross the posterior triangle of the neck, forming the supraclavicular nerves. It gives a branch to the phrenic nerve, while it is contained in the intertransverse space, and sometimes a branch to the Scalenus medius muscle. It also gives a branch to the Levator anguli scapulæ and to the Trapezius, which unites with the branch given off from the third nerve, and communicates beneath the muscle with the spinal accessory.

The **anterior divisions of the fifth, sixth, seventh, and eighth cervical nerves** are remarkable for their size. They are much larger than the preceding nerves, and are all of equal dimensions. They assist in the formation of the brachial plexus.

The Cervical Plexus.

The cervical plexus (Fig. 409) is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebræ, resting upon the Levator anguli scapulæ and Scalenus medius muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, *superficial* and *deep*, which may be thus arranged:

<i>Superficial</i>	{	Ascending .	{	Occipitalis minor. Auricularis magnus. Superficialis colli.
{	Descending .	Supraclavicular	{	Suprasternal. Supraclavicular. Supra-acromial.

<i>Deep</i> . . .	{	Internal . .	{	Communicating.
				Muscular.
				Communicantes hypoglossi.
				Phrenic.
	{	External . .	{	Communicating.
				Muscular.

Superficial Branches of the Cervical Plexus.

The **Occipitalis minor** (Fig. 415) arises from the second cervical nerve, sometimes also from the third; it curves round the posterior border of the Sterno-mastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the ear, supplying the integument, and communicating with the occipitalis major, the auricularis magnus, and with the posterior auricular branch of the facial.

This nerve gives off an *auricular branch*, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the auricularis magnus. This branch is occasionally derived from the great occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The **Auricularis Magnus** is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the Sterno-mastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into facial, auricular, and mastoid branches.

The *facial branches* pass across the parotid, and are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The *auricular branches* ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and pneumogastric nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.

The *mastoid branch* communicates with the occipitalis minor and the posterior auricular branch of the facial, and is distributed to the integument behind the ear.

The **Superficialis Colli** arises from the second and third cervical nerves, turns round the posterior border of the Sterno-mastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the anterior border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches which are distributed to the antero-lateral parts of the neck.

The *ascending branch* gives a filament which accompanies the external jugular vein; it then passes upward to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce that muscle and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The *descending branch* (occasionally represented by two or more filaments) pierces the Platysma, and is distributed to the integument of the side and front of the neck, as low as the sternum.

The **Descending or supraclavicular branches** arise from the third and fourth cervical nerves: emerging beneath the posterior border of the Sterno-mastoid, they descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

The *inner or suprasternal branches* cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sterno-mastoid, and supply the integument as far as the median line. They furnish one or two filaments to the sterno-clavicular joint.

The *middle* or *supraclavicular* branches cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The *external* or *supra-acromial* branches pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

FIG. 409.—Plan of the cervical plexus.

Deep Branches of the Cervical Plexus. Internal Series.

The **communicating branches** consist of several filaments, which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal, and sympathetic; of branches from all four cervical nerves to the superior cervical ganglion of the sympathetic, together with a branch from the fourth to the fifth cervical.

Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The **Communicans Hypoglōssi** (Fig. 406) consists usually of two filaments, one being derived from the second, and the other from the third, cervical. These filaments pass downward on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels (see page 756). Occasionally, the junction of these nerves takes place within the sheath.

The **Phrenic Nerve** (*internal respiratory of Bell*) arises chiefly from the fourth

cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the *Scalenus anticus*, and beneath the *Sterno-mastoid*, the posterior belly of the *Omo-hyoid*, and the *Transversalis colli* and *suprascapular* vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, which separately pierce that muscle and are distributed to its under surface.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right *vena innominata* and superior *vena cava*.

The *left nerve* is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. It enters the thorax behind the left innominate vein, and crosses in front of the *vagus* and the arch of the aorta and the root of the lung. In the thorax each phrenic nerve is accompanied by a branch of the internal mammary artery, the *comes nervi phrenici*.

Each nerve supplies filaments to the pericardium and pleura, and near the chest is joined by a filament from the sympathetic, and, occasionally, by one from the union of the *descendens hypoglossi* with the spinal nerves: this filament is found, according to Swan, only on the left side. It frequently receives a filament from the nerve to the *Subclavius* muscle. Branches have been described as passing to the peritoneum.

From the *right nerve* one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior *vena cava*. From the *left nerve* filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Deep Branches of the Cervical Plexus. External Series.

Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the *Sterno-mastoid* muscle, in the posterior triangle, and beneath the *Trapezius*.

Muscular branches are distributed to the *Sterno-mastoid*, *Trapezius*, *Levator anguli scapulæ*, and *Scalenus medius*.

The branch for the *Sterno-mastoid* is derived from the second cervical; the *Trapezius* and *Levator anguli scapulæ* receive branches from the third and fourth. The *Scalenus medius* is derived sometimes from the third, sometimes the fourth, and occasionally from both nerves.

The Brachial Plexus (Fig. 410).

The **Brachial Plexus** is formed by the union of the anterior divisions of the four lower cervical and the greater part of the first dorsal nerves, receiving usually a fasciculus from the fourth cervical nerve, and frequently one from the second dorsal nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communica-

tion is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement: the fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the *Scalenus medius* external to the outer border of the

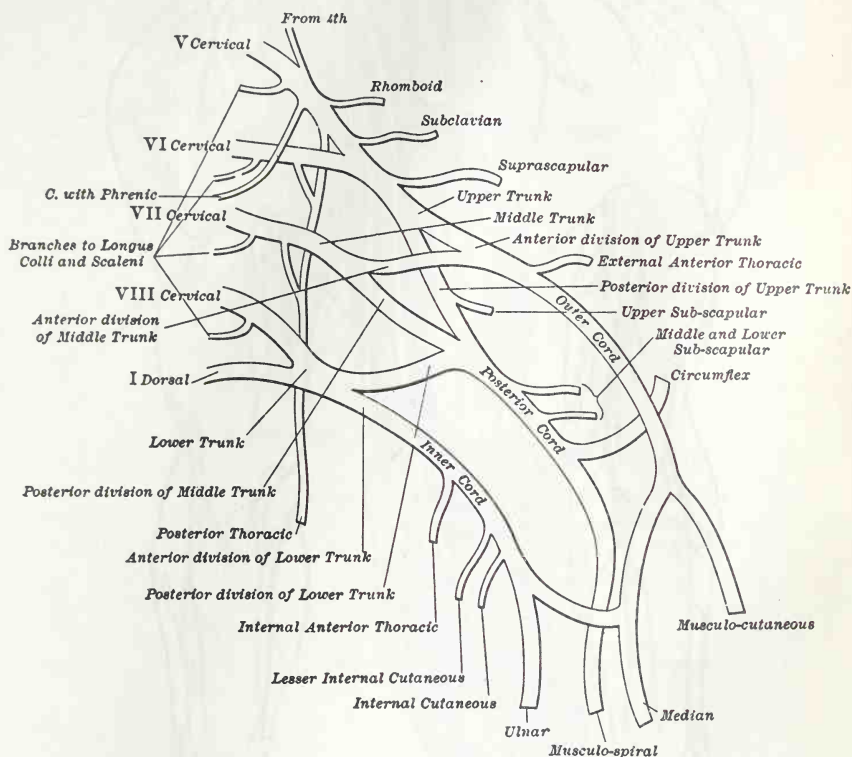

FIG. 410.—Plan of the brachial plexus.

Scalenus anticus, are blended into three trunks—an upper one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and a lower one, formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, each of these three trunks divides into two branches, an *anterior* and a *posterior*.¹ The anterior divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the *outer cord* of the brachial plexus. The anterior division of the lower trunk passes down on the inner side of the axillary artery in the middle of the axilla, and forms the *inner cord* of the brachial plexus. The posterior divisions of all three trunks unite to form the *posterior cord* of the brachial plexus, which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the upper trunk prior to its junction with the posterior division of the lower and middle trunks. The posterior cord divides into the circumflex and musculo-spiral nerves.

The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth nerve, and with the phrenic nerve by a branch from the

¹ The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.

FIG. 413.—Nerves of the left upper extremity.

scaeni muscles, and then above and to the outer side of the subclavian artery: it next passes behind the clavicle and Subclavius muscle, lying upon the first serra-

tion of the Serratus magnus, and the Subscapularis muscles. *In the axilla*, it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches.—The branches of the brachial plexus are arranged in two groups—viz., those given off above the clavicle, and those below that bone.

Branches above the Clavicle.

Communicating.
Muscular.

Posterior thoracic.
Suprascapular.

The communicating branch with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle. The communications with the sympathetic have already been referred to.

The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the four lower cervical nerves at their exit from the intervertebral foramina. The Rhomboid branch arises from the fifth cervical, pierces the Scalenus medius, and passes beneath the Levator anguli scapulæ, which it occasionally supplies, to the Rhomboid muscles. The nerve to the Subclavius is a small filament which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the third part of the subclavian artery to the Subclavius muscle, and is usually connected by a filament with the phrenic nerve.

The posterior thoracic nerve (*long thoracic, external respiratory of Bell*) (Fig. 413) supplies the Serratus magnus, and is remarkable for the length of its course. It sometimes arises by two roots from the fifth and sixth cervical nerves immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance of the Middle scalenus muscle, and, after emerging from it, the nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of its digitations.

The suprascapular nerve (Fig. 414) arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the Trapezius and the Omo-hyoid, it enters the supraspinous fossa below the transverse or suprascapular ligament, and, passing beneath the Supraspinatus muscle, curves round the external border of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

Branches below the Clavicle.

The branches given off below the clavicle are derived from the three cords of the brachial plexus, in the following manner:

From the outer cord arise the external anterior thoracic nerve, the musculo-cutaneous, and the outer head of the median.

From the inner cord arise the internal anterior thoracic nerve, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg), the ulnar, and inner head of the median.

From the posterior cord arise two of the three subscapular nerves, the third taking origin from the posterior division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These may be arranged according to the parts they supply :

To the chest	Anterior thoracic.
To the shoulder	{ Subscapular.
	{ Circumflex.
	{ Musculo-cutaneous.
	{ Internal cutaneous.
To the arm, forearm, and hand .	{ Lesser internal cutaneous.
	{ Median.
	{ Ulnar.
	{ Musculo-spiral.

The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows :

External anterior thoracic	from 5th, 6th, and 7th cervical.
Internal anterior thoracic	“ 8th cervical and 1st dorsal.
Subscapular	“ 5th, 6th, 7th, and 8th cervical.
Circumflex	“ 5th and 6th cervical.
Musculo-cutaneous	“ 5th and 6th cervical.
Internal cutaneous	“ 8th cervical and 1st dorsal.
Lesser internal cutaneous	“ 1st dorsal.
Median	“ 6th, 7th, and 8th cervical, and 1st dorscl.
Ulnar	“ 8th cervical and 1st dorsal.
Musculo-spiral	“ 6th, 7th, and 8th cervical, sometimes also from the 5th.

The **Anterior Thoracic Nerves** (Fig. 413), two in number, supply the Pectoral muscles.

The *external* or superficial nerve, the larger of the two, arises from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major. It sends down a communicating filament to join the internal nerve, which forms a loop round the inner side of the axillary artery.

The *internal* or deep nerve arises from the inner cord, and through it from the eighth cervical and first dorsal. It passes behind the first part of the axillary artery, then curves forward between the axillary artery and vein, and joins with the filament from the anterior nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some two or three branches pass through the muscle to supply the Pectoralis major.

The **Subscapular Nerves**, three in number, supply the Subscapularis, Teres major, and Latissimus dorsi muscles. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The *upper subscapular nerve*, the smallest, enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The *lower subscapular nerve* enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The *middle* or *long subscapular*, the largest of the three, follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, through which it may be traced as far as its lower border.

The **Circumflex Nerve** (Fig. 414) supplies some of the muscles and the integument of the shoulder and the shoulder-joint. It arises from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle,

and passes downward and outward to the lower border of that muscle. It then winds backward in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Teres minor, below by the Teres major, internally by the long head of the Triceps, and externally by the neck of the humerus, and divides into two branches.

The *upper branch* winds round the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part.

The *lower branch*, at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filament to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid, as well as that covering the long head of the Triceps.

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis.

The **Musculo-cutaneous Nerve** (Fig. 413) (*external cutaneous or perforans Casserii*)¹ supplies some of the muscles of the arm and the integument of the forearm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coraco-brachialis muscle, passes obliquely between the Biceps and Brachialis anticus to the outer side of the arm, and, a little above the elbow, winds round the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous. This nerve, in its course through the arm, supplies the Coraco-brachialis, Biceps, and the greater part of the Brachialis anticus muscles. The branch to the Coraco-brachialis is given off from the nerve close to its origin, and in some instances, especially in early life, as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coraco-brachialis. The nerve also sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery, and a filament, from the branch supplying the Brachialis anticus, to the elbow-joint.

The cutaneous portion of the nerve passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The *anterior branch* descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and the palmar cutaneous branch of the median.

The *posterior branch* passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculo-spiral.

The musculo-cutaneous nerve presents frequent irregularities. It may adhere for some distance to the median and then pass outward, beneath the Biceps, instead of through the Coraco-brachialis. Frequently some of the fibres of the median run for some distance in the musculo-cutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to join the musculo-cutaneous. Instead of piercing the Coraco-brachialis, the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator teres, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The **Internal Cutaneous Nerve** (Fig. 413) is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar and

¹ See foot-note, page 726.

internal head of the median, and, at its commencement, is placed on the inner side of the axillary, and afterward of the brachial artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The *anterior branch*, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve.

The *posterior branch* passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument. It communicates, above the elbow, with the lesser internal cutaneous, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan).

The **Lesser Internal Cutaneous Nerve** (*nerve of Wrisberg*) (Fig. 413) is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord with the internal cutaneous and ulnar nerves, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of, the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and intercosto-humeral are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely from the intercosto-humeral.

The **Median Nerve** (Fig. 413) has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and the musculo-spiral and radial nerves. It arises by two roots, one from the outer, and one from the inner, cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. It receives filaments from the sixth, seventh, and eighth cervical and the first dorsal. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus. In the forearm it passes between the two heads of the Pronator radii teres, and descends beneath the Flexor sublimis, lying on the Flexor profundus, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis, beneath, and rather to the radial side of, the tendon of the Palmaris longus, covered by the integument and fascia. It then passes beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a branch of the anterior interosseous artery.

Branches.—With the exception of the nerve to the Pronator teres, which sometimes arises above the elbow-joint, the median nerve gives off no branches in the arm. In the forearm its branches are muscular, anterior interosseous, and palmar cutaneous, and, according to Rüdinger and Macalister, two articular twigs to the elbow-joint.

The *muscular branches* supply all the superficial muscles on the front of the forearm except the Flexor carpi ulnaris. These branches are derived from the nerve near the elbow.

The *anterior interosseous* supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus and wrist-joint.

The *palmar cutaneous branch* arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the *outer* supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the *inner* supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the *palm of the hand* the median nerve is covered by the integument and palmar fascia and crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the *external* supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the *internal* supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers.

The *branch to the muscles of the thumb* is a short nerve which divides to supply the Abductor, Opponens, and the superficial head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The *digital branches* are five in number. The *first* and *second* pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The *third* passes along the radial side of the index finger, and supplies the First lumbricalis muscle. The *fourth* subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbrical muscle. The *fifth* supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies round and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries.

The **Ulnar Nerve** (Fig. 413) is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first dorsal nerves. At its commencement it lies to the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. At the elbow it rests upon the back of the

inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris. *In the forearm* it descends in a perfectly straight course along its ulnar side, lying upon the Flexor profundus digitorum, its upper half being covered by the Flexor carpi ulnaris, its lower half lying on the outer side of the muscle, covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to its inner side. *At the wrist* the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side of and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, superficial and deep palmar.

The branches of the ulnar nerve are—

In the forearm	{	Articular (elbow). Muscular. Cutaneous. Dorsal cutaneous. Articular (wrist).	In the hand	{	Superficial palmar. Deep palmar.
----------------	---	--	-------------	---	-------------------------------------

The *articular branches* distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle and olecranon.

The *muscular branches* are two in number—one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The *cutaneous branch* arises from the ulnar nerve about the middle of the forearm, and divides into two branches.

One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch (*palmar cutaneous*) lies on the ulnar artery, which it accompanies to the hand, some filaments entwining round the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The *dorsal cutaneous branch* arises about two inches above the wrist; it passes backward beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches; one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying them; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the palmar digital branches of the ulnar.

The *superficial palmar branch* supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The *deep palmar branch*, accompanied by the deep branch of the ulnar artery, passes between the Abductor and Flexor brevis minimi digiti muscles; it then perforates the Opponens minimi digiti and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index

finger, it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint.

It will be remembered that the inner part of the Flexor profundus digitorum is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar.

FIG. 414.—The suprascapular, circumflex, and musculo-spiral nerves.

The **Musculo-spiral Nerve** (Fig. 414), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand. It arises from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. It receives filaments from the sixth, seventh, and eighth, and sometimes also from the fifth cervical nerves. At its commencement it is placed behind the axillary and upper part of the brachial arteries, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds round the humerus in the musculo-spiral groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle. It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus to the front of the external condyle, where it divides into the radial and posterior interosseous nerves.

The branches of the musculo-spiral nerve are—

Muscular.

Cutaneous.

Radial.

Posterior interosseous.

The muscular branches are divided into internal, posterior, and external;

they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.

The internal muscular branches supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is therefore frequently spoken of as the *ulnar collateral*.

The posterior muscular branch, of large size, arises from the nerve in the groove between the Triceps and the humerus. It divides into branches which supply the outer and inner head of the Triceps and Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The external muscular branches supply the Supinator longus, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus.

The *cutaneous branches* are three in number, one internal and two external.

The internal cutaneous branch arises in the axillary space with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral, with which it communicates.

The two external cutaneous branches perforate the outer head of the Triceps at its attachment to the humerus. The upper and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The lower branch pierces the deep fascia below the insertion of the Deltoid, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The *radial nerve* passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It quits the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into four digital nerves, which are distributed as follows: The first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.¹ The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The *Posterior Interosseous Nerve* winds to the back of the forearm round the outer side of the radius, passes between the two planes of fibres of the Supinator brevis, and is prolonged downward between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies

¹ According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx, and the one to the middle and ring fingers not higher than the first phalangeal joint (*London Hosp. Gaz.*, vol. iii., p. 319).

all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

Surgical Anatomy.—The brachial plexus may be ruptured by traction on the limb, leading to complete paralysis. In these cases the lesion would appear to be rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In the axilla any of the nerves forming the brachial plexus may be injured in a wound of this part, the median being the one which is most frequently damaged from its exposed position, and the musculo-spiral, on account of its sheltered and deep position, being the least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as "crutch paralysis." In these cases the musculo-spiral appears most frequently to be the nerve which is chiefly implicated; the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course round the surgical neck of the humerus, it is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Mr. Hilton takes the circumflex nerve as an illustration of a law which he lays down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles also which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers is effected by that portion of the *Flexor profundus digitorum* which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the *Interossei*. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the *Flexor carpi ulnaris*. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the last phalanx. In order to expose the median nerve for the purpose of stretching an incision should be made along the radial side of the tendon of the *Palmaris longus*, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction; there is inability to spread out the fingers from paralysis of the *Interossei*; and there is inability to adduct the thumb. Sensation is lost or impaired in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the *Flexor carpi ulnaris*, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculo-spiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows or to be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This is known as "drop-wrist." The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the *Interossei*, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but it is possible to a certain extent if the forearm is flexed so as to allow of the action of the *Biceps*. The power of extension of the forearm is lost on account of paralysis of the *Triceps*. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the *Supinator longus*, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the *Supinator longus* the nerve will be found lying beneath it, on the *Brachialis anticus*.

THE DORSAL NERVES (Fig. 415).

The **Dorsal Nerves** are twelve in number on each side. The first appears between the first and second dorsal vertebræ, and the last between the last dorsal and first lumbar.

The *roots of the dorsal nerves* are of small size, and vary but slightly from the

second to the last. Both roots are very slender, the posterior roots only slightly exceeding the anterior in thickness. They gradually increase in length from above downward, and in the lower part of the dorsal region pass down in contact with the spinal cord for a distance equal to the height of at least two vertebræ, before they emerge from the spinal canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The first, the second, and the last dorsal nerves are peculiar in some respects.

Posterior Divisions of the Dorsal Nerves.

The posterior divisions of the dorsal nerves, which are smaller than the anterior, pass backward between the transverse processes, and divide into internal and external branches.

The *internal branches of the six upper nerves* pass inward between the Semispinalis dorsi and Multifidus spinæ muscles, which they supply, and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the Multifidus spinæ, without giving off any cutaneous filaments.

The *external branches* increase in size from above downward. They pass through the Longissimus dorsi to the cellular interval between it and the Iliocostalis, and supply those muscles, as well as their continuations upward to the head, and the Levatores costarum; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi in a line with the angles of the ribs, and then ramify in the integument.

The *cutaneous branches of the posterior primary divisions of the dorsal nerves* are twelve in number. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the Serratus posticus inferior and Latissimus dorsi in a line with the angles of the ribs, and then ramify in the integument.

Anterior Divisions of the Dorsal Nerves.

The anterior divisions of the dorsal nerves (*intercostal nerves*) are twelve in number on each side. They are, for the most part, distributed to the parietes of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the other spinal nerves. Each nerve is connected with the adjoining ganglia of the sympathetic by one or two filaments. The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietes of the chest. The six lower supply the parietes of the chest and abdomen, the last one sending a cutaneous filament to the buttock.

The First Dorsal Nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the *first intercostal nerve*, and terminates on the front of the chest by forming the first anterior cutaneous nerve of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercosto-humeral. It frequently receives a connecting twig from the second dorsal nerve, which passes upward over the neck of the second rib.

FIG. 415.—Superficial and deep distribution of the posterior divisions of the spinal nerves (after Hirschfeld and Leveillé). On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinae divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin. *a a*. Lesser occipital nerve from the cervical plexus. 1. External muscular branches of the first cervical nerve, and union by a loop with the second. 2, placed on the Rectus capitis posticus major muscle, marks the great occipital nerve, passing round the short muscles and piercing the Complexus: the external branch is seen to the outside. 3. External branch from the posterior division of the third nerve. 3'. Its internal branch, sometimes called the third occipital. 4' to 8'. The internal branches of the several corresponding nerves on the left side. The external branches of these nerves, proceeding to muscles, are displayed on the right side, *d 1* to *d 6*, and thence to *d 12*. External muscular branches of the posterior divisions of the twelve dorsal nerves on the right side, *d 1'* to *d 6'*. The internal cutaneous branches of the six upper dorsal nerves on the left side, *d 7'* to *d 12'*. Cutaneous twigs from the external branches of the six lower dorsal nerves. *l l*. External branches from the posterior divisions of several lumbar nerves on the right side, piercing the muscles, the lower descending over the gluteal region. *l' l'*. The same, more superficially, on the left side. *s s*. The issue and union by loops of the posterior divisions of four sacral nerves on the right side. *n n*. Some of those distributed to the skin on the left side.

The Upper Dorsal Nerves.—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are

confined to the parietes of the thorax, and are named *upper* or *pectoral intercostal nerves*. They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleura and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membrane, and Pectoralis major muscle, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax; the branch from the second nerve is joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posticus superior, and Triangularis sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.

Lateral Cutaneous Nerves.—These are derived from the intercostal nerves, midway between the vertebræ and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, anterior and posterior.

The *anterior branches* are reflected forward to the side and the fore part of the chest, supplying the integument of the chest and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique.

The *posterior branches* are reflected backward to supply the integument over the scapula and over the Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It is named, from its origin and distribution, the *intercosto-humeral nerve* (Fig. 413). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm, communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm.

The Lower Dorsal Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, and the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib; hence these nerves are named *lower* or *abdominal intercostal nerves*. They have (with the exception of the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the anterior cutaneous nerves of the abdomen. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off lateral cutaneous branches which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed to the integument of the abdomen and back; the anterior branches supply the digitations of the External oblique muscle and extend downward and forward nearly as far as the margin of the Rectus; the posterior branches pass backward to supply the skin over the Latissimus dorsi.

The last dorsal is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib, and passes under the external arcuate ligament of the Diaphragm. It then runs in front of the Quadratus lumborum, perforates the Transversalis, and passes forward between it and the Internal oblique, to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the *dorsilumbar nerve*, which descends in the substance of the Quadratus lumborum. It gives a branch to the Pyramidalis muscle.

The *lateral cutaneous branch of the last dorsal* is remarkable for its large size; it perforates the Internal and External oblique muscles, passes downward over the crest of the ilium in front of the iliac branch of the ilio-hypogastric (Fig. 422), and is distributed to the integument of the front part of the gluteal region, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and a posterior branch, like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach;" the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical importance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near the origin the pain is referred to their peripheral terminations. Thus in Pott's disease of the spine children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more general diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tabes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin derived from the lower intercostal nerves are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBAR NERVES.

The lumbar nerves are five in number on each side. The first appears between the first and second lumbar vertebræ, and the last between the last lumbar and the base of the sacrum.

The roots of the lumbar nerves are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller, but there is not the

same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, posterior and anterior.

The Posterior Divisions of the Lumbar Nerves.

The posterior divisions of the lumbar nerves (Fig. 415) diminish in size from above downward; they pass backward between the transverse processes, and divide into internal and external branches.

The *internal branches*, the smaller, pass inward close to the articular processes of the vertebræ, and supply the Multifidus spinæ and Interspinales muscles.

The *external branches* supply the Erector spinæ and Intertransverse muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major.

The Anterior Divisions of the Lumbar Nerves.

The anterior divisions of the lumbar nerves increase in size from above downward. At their origin they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries round the sides of the bodies of the vertebræ, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the four upper nerves are connected together in this situation by anastomotic loops, and form the *lumbar plexus*. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the *lumbo-sacral cord*.

The Lumbar Plexus (Fig. 416).

The *lumbar plexus* is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last dorsal by a slender branch, the *dorsi-lumbar nerve*; it is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. It is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse process of the lumbar vertebræ.

The mode in which the plexus is arranged varies in different subjects. It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves, somewhat in the following manner: The first lumbar nerve receives a branch from the last dorsal, and gives off a larger branch, which subdivides into the ilio-hypogastric and ilio-inguinal; a communicating branch which passes down to the second lumbar nerve; and a third branch which unites with a branch of the second lumbar to form the genito-crural nerve. The second, third, and fourth lumbar nerves divide into an anterior and a posterior division. The anterior division of the second divides into two branches, one of which joins with the above-mentioned branch of the first nerve to form the genito-crural; the other unites with the anterior division of the third nerve, and a part of the anterior division of the fourth nerve to form the obturator nerve. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerves divide into two branches, a smaller branch from each uniting to form the external cutaneous nerve, and a larger branch from each, which join with

the whole of the posterior division of the fourth lumbar nerve to form the anterior crural. The accessory obturator, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

FIG. 416.—Plan of the lumbar plexus.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-crural from the first and second nerves; the external cutaneous from the second and third; the anterior crural and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

The branches of the lumbar plexus are—the

Ilio-hypogastric.

Ilio-inguinal.

Genito-crural.

External cutaneous.

Anterior crural.

Obturator.

Accessory obturator.

The **Ilio-hypogastric Nerve** arises from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part near the crest of the ilium, and divides between it and the Internal oblique into two branches, iliac and hypogastric.

The *iliac branch* pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (Fig. 422). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The *hypogastric branch* (Fig. 418) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about

an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

The **Ilio-inguinal Nerve**, smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas just below the ilio-hypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the fore part of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing filaments to it; and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male and to the labium majus in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

FIG. 417.—The lumbar plexus and its branches.

The **Genito-crural Nerve** arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebræ; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a genital and a crural branch.

FIG. 418.—Cutaneous nerves of lower extremity. Front view.

The *genital branch* passes outward on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; it then descends along

FIG. 419.—Nerves of the lower extremity. Front view.

the back part of the spermatic cord to the scrotum, and supplies, in the male, the Cremaster muscle. In the female, it accompanies the round ligament, and is lost upon it.

The *crural branch* descends on the external iliac artery, sending a few filaments round it, and, passing beneath Poupart's ligament to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The **External Cutaneous Nerve** arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and crosses the Iliacus muscle obliquely, toward the anterior superior spine of the ilium. It then passes under Poupart's ligament and over the Sartorius muscle into the thigh, where it divides into two branches, anterior and posterior.

The *anterior branch* descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The *posterior branch* pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integument from the crest of the ilium as far as the middle of the thigh.

The **Obturator Nerve** supplies the obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the second, the third, and the fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas muscle, and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus (Fig. 257), and lower down by the Adductor brevis muscle.

The *anterior branch* (Fig. 419) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch, to the thigh and leg. When this is so, this *occasional cutaneous* branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small, its place is supplied by the internal cutaneous nerve.

The *posterior branch of the obturator nerve* pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which

supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. One of the branches gives off a filament to the knee-joint.

The *articular branch for the knee-joint* is sometimes absent; it perforates the lower part of the Adductor magnus, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

The **Accessory Obturator Nerve** (Fig. 417) is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally it is very small, and becomes lost in the capsule of the hip-joint.

The **Anterior Crural Nerve** (Figs. 417, 419) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor fasciæ femoris; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot; and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from it at the lower part of its outer border, and passes down between it and the Iliacus, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart's ligament it is separated from the femoral artery by a portion of the Psoas muscle, and lies beneath the iliac fascia.

Within the abdomen the anterior crural nerve gives off from its outer side some small branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies: it occasionally arises higher than usual, or it may arise lower down in the thigh.

External to the pelvis the following branches are given off:

From the Anterior Division.

Middle cutaneous.
Internal cutaneous.
Muscular.

From the Posterior Division.

Long saphenous.
Muscular.
Articular.

The *middle cutaneous nerve* (Fig. 418) pierces the fascia lata (generally the Sartorius also) about three inches below Poupart's ligament, and divides into two branches, which descend in immediate proximity along the fore part of the thigh, to supply the integument as low as the front of the knee, where it communicates with the internal cutaneous and the patellar branch of the internal saphenous nerve, to form the patellar plexus. In the upper part of the thigh the outer division of the middle cutaneous communicates with the crural branch of the genito-crural nerve.

The *internal cutaneous nerve* passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, anterior and posterior or internal.

The *anterior branch* runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the nervus cutaneus patellæ, a branch of the internal saphenous nerve.

The *posterior or internal branch* descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with

the long saphenous nerve, and gives off several cutaneous branches. The nerve then passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (Fig. 419). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; and a third pierces the fascia at its lower third.

Muscular Branches of the Anterior Division.—The nerve to the *Pectineus* is often duplicated; it arises from the anterior crural immediately below Poupart's ligament, and passes inward behind the femoral sheath to enter the anterior surface of the muscle. The nerve to the *Sartorius* arises in common with the middle cutaneous.

The long or internal saphenous nerve is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then quits the artery, and descends vertically along the inner side of the knee, beneath the Sartorius, pierces the fascia lata opposite the interval between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the inner side of the leg, accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

Branches.—The long saphenous nerve about the middle of the thigh gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

At the inner side of the knee it gives off a large patellar branch (*nervus cutaneus patellæ*) which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the *plexus patellæ*. The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve.

The muscular branches of the posterior division supply the four parts of the Quadriceps extensor muscle.

The branch to the *Rectus muscle* enters its under surface high up, sending off a small filament to the hip-joint.

The branch to the *Vastus externus*, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The branch to the *Vastus internus* is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

The *branch to the Crureus* enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Sub-crureus and the knee-joint.

The *articular branch to the hip-joint* is derived from the nerve to the Rectus.

The *articular branches to the knee-joint* are three in number. One, a long, slender filament, is derived from the nerve to the Vastus externus; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscular fibres, and accompanies the deep branch of the *anastomotica magna* artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

THE SACRAL AND COCCYGEAL NERVES.

The *sacral nerves* are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The *roots of the upper sacral nerves* are the largest of all the spinal nerves; while those of the lowest sacral and coccygeal nerve are the smallest. They are longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length, and the appearance they present in connection with their attachment to the spinal cord, the roots of origin of these nerves are called collectively the *cauda equina*.

Each sacral and coccygeal nerve separates into two divisions, posterior and anterior.

The *posterior divisions of the sacral nerves* (Fig. 420) are small, diminish in

FIG. 420.—The posterior sacral nerves.

size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The *three upper ones* are covered, at their exit from the sacral canal, by the *Multifidus spinæ*, and divide into internal and external branches.

The *internal branches* are small, and supply the *Multifidus spinæ*.

The *external branches* join with one another, and with the last lumbar and fourth sacral nerves, in the form of loops on the posterior surface of the sacrum. From these loops branches pass to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the *Gluteus maximus*. Cutaneous branches from this second series of loops, usually two or three in number, pierce the *Gluteus maximus* along a line drawn from the posterior superior spine of the ilium to the tip of the coccyx. They supply the integument over the posterior part of the gluteal region.

The *posterior divisions of the two lower sacral nerves* are situated below the *Multifidus spinæ*. They are of small size, and do not divide into internal and external branches, but join with each other, and with the coccygeal nerve, so as to form loops on the back of the sacrum, filaments from which supply the *Extensor coccygis* and the integument over the coccyx.

The *coccygeal nerve* divides into its anterior and posterior divisions in the spinal canal. The *posterior division* is the smaller. It does not divide, but receives, as already mentioned, a communicating branch from the last sacral, and is lost in the integument over the back of the coccyx.

The *anterior divisions of the sacral nerves* diminish in size from above down-

FIG. 421.—Side view of pelvis, showing sacral nerves.

ward. The four upper ones emerge from the anterior sacral foramina: the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forward between the sacrum and the coccyx. All the anterior sacral nerves communicate with the sacral ganglia of the sympathetic at their exit from the sacral foramina. The *first nerve*, of large size, unites with the *lumbo-sacral cord*, formed by the fifth lumbar, and a branch from the fourth lum-

bar. The *second*, equal in size to the preceding, and the *third*, about one-fourth the size of the second, unite with this trunk, and form, with a small fasciculus from the fourth, the *sacral plexus*, a visceral branch being given off from the third nerve to the bladder.

The *fourth anterior sacral nerve* sends a branch to join the sacral plexus. The remaining portion of the nerve divides into visceral and muscular branches, and a communicating filament descends to join the fifth sacral nerve. The *visceral branches* are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The *muscular branches* are distributed to the Levator ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding round the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The *fifth anterior sacral nerve*, after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The *anterior division of the coccygeal nerve* is a delicate filament which escapes at the termination of the sacral canal; it passes downward behind the rudimentary transverse process of the first piece of the coccyx, and curves forward through the notch between the first and second pieces, piercing the Coccygeus muscle, and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

The Sacral Plexus (Fig. 421).

The *sacral plexus* is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves, and part of that of the fourth. These nerves proceed in different directions: the upper ones obliquely downward and outward, the lower ones nearly horizontally, and they all unite into two cords: an *upper* and larger, which is formed by the lumbo-sacral cord with the first, second, and the greater part of the third sacral nerves; and a *lower* and smaller, formed by the remainder of the third, with a portion of the fourth sacral nerve. The upper cord is prolonged into the great sciatic nerve and the lower into the pudic. Frequently a small filament is given off from the second sacral nerve to join the lower cord.

The sacral plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Piriformis, and is covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis.

The branches of the sacral plexus are:

Collateral branches	{	Muscular.
		Superior gluteal.
		Inferior gluteal.
		Small sciatic.
Terminal branches	{	Perforating cutaneous.
		Pudic.
		Great sciatic.

The **Muscular branches** supply the *Pyriformis*, *Obturator internus*, the two *Gemelli*, and the *Quadratus femoris*. The branch to the *Pyriformis* arises from the upper two sacral nerves before they enter the plexus; the branch to the *Obturator internus* arises at the junction of the lumbo-sacral and first sacral nerves: it passes out of the pelvis through the great sacro-sciatic foramen below the *Pyriformis*, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen, to enter the inner surface of the *Obturator internus*; the branch to the *Gemellus superior* arises in common with the nerve to the *Obturator internus*: it enters the muscle at the upper part of its posterior surface; the small branch to the *Gemellus inferior* and *Quadratus femoris* also arises from the upper part of the plexus: it passes through the great sacro-sciatic foramen below the *Pyriformis*, and courses down beneath the great sciatic nerve, the *Gemelli* and tendon of the *Obturator internus*, and supplies the muscles on their deep or anterior surface. It gives off an articular branch to the hip-joint. A second articular branch is occasionally derived from the upper part of the sacral plexus.

The **Superior Gluteal Nerve** (Fig. 423) arises from the back part of the lumbo-sacral cord, with some filaments from the first sacral nerve; it passes from the pelvis through the great sacro-sciatic foramen above the *Pyriformis* muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The *superior branch* follows the line of origin of the *Gluteus minimus*, and supplies the *Gluteus medius*.

The *inferior branch* crosses obliquely between the *Gluteus minimus* and *medius*, distributing filaments to both these muscles, and terminates in the *Tensor fasciæ femoris*, extending nearly to its lower end.

The **Inferior Gluteal** arises from the lumbo-sacral cord and first and second sacral nerves, and is intimately connected with the small sciatic at its origin. It passes out of the pelvis through the great sciatic notch, beneath the *Pyriformis* muscle, and, dividing into a number of branches, enters the *Gluteus maximus* muscle on its under surface.

The **Small Sciatic Nerve** (Fig. 423) supplies the integument of the perineum and back part of the thigh and leg. It is usually formed by the union of two branches, which arise from the second and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the *Pyriformis* muscle, descends beneath the *Gluteus maximus* with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the *fascia lata* and over the long head of the *Biceps*, to the lower part of the popliteal region, where it pierces the *fascia* and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The branches of the small sciatic nerve are all cutaneous, and are grouped as follows: gluteal, perineal, and femoral.

The *gluteal cutaneous branches (ascending)* consist of two or three filaments, which turn upward round the lower border of the *Gluteus maximus* to supply the integument covering the lower and outer part of that muscle.

The *perineal cutaneous branches* are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the *inferior pudendal*, curves forward below the *tuber ischii*, pierces the *fascia lata*, and passes forward beneath the superficial *fascia* of the perineum to be distributed to the integument of the scrotum in the male and the labium in the female, communicating with the superficial perineal and inferior hemorrhoidal nerves.

FIG. 422.—Cutaneous nerves of lower extremity. Posterior view.

FIG. 423.—Nerves of the lower extremity.¹ Posterior view.

¹ N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

The *femoral cutaneous branches (descending)* are numerous filaments, derived from both sides of the nerves, which are distributed to the back, inner, and outer sides of the thigh, to the skin covering the popliteal space, and to the upper part of the leg.

The **Perforating Cutaneous Nerve** usually arises from the second and third sacral nerves, and is of small size. It is continued backward through the great sacro-sciatic ligament, and, winding round the lower border of the *Gluteus maximus*, supplies the integument covering the inner and lower part of that muscle.

The **Pudic Nerve** is the direct continuation of the lower cord of the sacral plexus, and derives its fibres from the third and fourth sacral nerves, and frequently from the second also. It leaves the pelvis through the great sacro-sciatic foramen, below the *Pyriformis*. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischio-rectal fossa, being contained in a sheath of the obturator fascia, termed *Alcock's canal*, and divides into two terminal branches, the perineal nerve and the dorsal nerve of the penis or clitoris. Before its division it gives off the inferior hemorrhoidal nerve.

The *inferior hemorrhoidal nerve* is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the *Sphincter ani externus* and to the integument round the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perineum.

The *perineal nerve*, the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The *posterior* or *external branch* pierces the base of the triangular ligament of the urethra, and passes forward along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the skin of the scrotum. It communicates with the inferior hemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The *anterior* or *internal branch* also pierces the base of the triangular ligament, and passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The muscular branches are distributed to the *Transversus perinæi*, *Accelerator urinæ*, *Erector penis*, and *Compressor urethræ*. A distinct branch is given off from the nerve to the *Accelerator urinæ*, which pierces this muscle, and supplies the *corpus spongiosum*, ending in the mucous membrane of the urethra. This is the nerve to the bulb.

The *dorsal nerve of the penis* is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; it then runs forward along the inner margin of the ramus of the os pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer it gives a branch to the *corpus cavernosum*, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans, to which it is distributed.

In the female the dorsal nerve is very small, and supplies the clitoris.

The **Great sciatic nerve** (Fig. 423) supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the continuation of the upper division of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the *Pyriformis* muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh, to about its lower third, where it divides into two large branches, the *internal* and *external popliteal nerves*.

This division may take place at any point between the sacral plexus and the

lower third of the thigh. When the division occurs at the plexus, the two nerves descend together side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the *Pyramiformis* muscle. As the nerve descends along the back of the thigh, it rests upon the posterior surface of the ischium, the nerve to the *Quadratus femoris*, and the *External rotator* muscles, in company with the small sciatic nerve and artery, being covered by the *Gluteus maximus*; lower down, it lies upon the *Adductor magnus*, and is covered by the long head of the *Biceps*.

The *branches* of the nerve, before its division, are articular and muscular.

The *articular branches* arise from the upper part of the nerve; they supply the hip-joint, perforating the posterior part of its fibrous capsule posteriorly. These branches are sometimes derived from the sacral plexus.

The *muscular branches* are distributed to the flexors of the leg: viz., the *Biceps*, *Semitendinosus*, and *Semimembranosus*, and a branch to the *Adductor magnus*. These branches are given off beneath the *Biceps* muscle.

The *Internal Popliteal Nerve*, the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the *Popliteus* muscle, where it passes with the artery beneath the arch of the *Soleus* and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the *Gastrocnemius*.

The *branches* of this nerve are—articular, muscular, and a cutaneous branch, the *communicans tibialis nerve*.

The *articular branches*, usually three in number, supply the knee-joint: two of these branches accompany the superior and inferior internal articular arteries, and a third, the *azygos articular artery*.

The *muscular branches*, four or five in number, arise from the nerve as it lies between the two heads of the *Gastrocnemius* muscle; they supply that muscle, the *Plantaris*, *Soleus*, and *Popliteus*. The filaments which supply the *Popliteus* turn round its lower border and are distributed to its deep surface.

The *communicans tibialis* descends between the two heads of the *Gastrocnemius* muscle, and about the middle of the back of the leg pierces the deep fascia, and joins a communicating branch (*communicans peronei*) from the external popliteal nerve to form the external or short saphenous (Fig. 422). The external saphenous nerve, formed by the communicating branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It winds round the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic.

The *Posterior Tibial Nerve* (Fig. 423) commences at the lower border of the *Popliteus* muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the *external* and *internal plantar nerves*. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The *branches of the posterior tibial nerve* are muscular, calcaneo-plantar, and articular.

The *muscular branches* arise either separately or by a common trunk from the upper part of the nerve. They supply the *Soleus*, *Tibialis posticus*, *Flexor longus digitorum*, and *Flexor longus hallucis* muscles; the branch to the latter muscle

accompanying the peroneal artery. The branch to the Soleus enters its deep surface, while the branch which this muscle receives from the internal popliteal enters its superficial aspect.

The *calcaneo-plantar* (*internal calcanean*) branch perforates the internal annular ligament, and supplies the integument of the heel and inner side of the sole of the foot.

The *articular branch* is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **Internal Plantar Nerve** (Fig. 424), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forward between this muscle and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into four digital branches, and communicates with the external plantar nerve.

Branches.—In its course the internal plantar nerve gives off *cutaneous branches*, which pierce the plantar fascia and supply the integument of the sole of the foot; *muscular branches*, which supply the Abductor hallucis and Flexor brevis digitorum; *articular branches*, to the articulations of the tarsus and metatarsus; and *four digital branches*. The three outer branches pass between the divisions of the plantar fascia in the clefts between the toes: the first (innermost) branch becomes cutaneous farther back between the Adductor hallucis and Flexor brevis digitorum. They are distributed in the following manner: The *first* supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the *second* bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the *third digital branch* supplies the adjacent sides of the second and third toes; the *fourth* supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve. Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The **External Plantar Nerve**, the smaller of the two, completes the nervous supply to the structures of the sole of the foot, being distributed to the little toe and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Abductor minimi digiti divides into a superficial and a deep branch. Before its division it supplies the Flexor accessorius and Abductor minimi digiti.

The *superficial branch* separates into two digital nerves: one, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti,

FIG. 424.—The plantar nerves.

¹See foot-note, page 448.

and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The *deep or muscular branch* accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **External Popliteal or Peroneal Nerve** (Fig. 423), about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds round the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the anterior tibial and musculo-cutaneous nerves.

The *branches of the peroneal nerve*, previous to its division, are articular and cutaneous.

The *articular branches* are three in number; two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The *cutaneous branches*, two or three in number, supply the integument along the back part and outer side of the leg; one of these, larger than the rest, the *communicans peronei*, arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans tibialis to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued as far down as the heel.

The **Anterior Tibial Nerve** (Fig. 419) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely forward beneath the Extensor longus digitorum to the fore part of the interosseous membrane, and gets into relation with the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The *branches of the anterior tibial nerve* in its course through the leg are the muscular branches to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an *articular branch* to the ankle-joint.

The *external or tarsal branch of the anterior tibial* passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum. From the enlargement three minute *interosseous branches* are given off which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The *internal branch*, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two branches, which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an *interosseous branch* to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The **Musculo-cutaneous Nerve** (Fig. 419) supplies the muscles on the fibular

side of the leg and the integument of the dorsum of the foot. It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off muscular branches to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The *internal branch of the musculo-cutaneous nerve* passes in front of the ankle-joint, and divides into two branches, one of which supplies the inner side of the great toe, the other, the adjacent sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and joining with the anterior tibial nerve, between the great and second toes.

The *external branch*, the smaller, passes along the outer side of the dorsum of the foot, and divides into two branches, the inner being distributed to the contiguous sides of the third and fourth toes, the outer to the opposed sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve.

The branches of the musculo-cutaneous nerve supply all the toes excepting the outer side of the little toe, and the adjoining sides of the great and second toes, the former being supplied by the external saphenous, and the latter by the internal branch of the anterior tibial. It frequently happens, however, that some of the outer branches of the musculo-cutaneous are absent, their place being then taken by branches of the external saphenous nerve.

Surgical Anatomy.—The lumbar plexus passes through the Psoas muscle, and, therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the principal reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart's ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upward through the action of the Cremaster muscle, supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the ascending ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon, and its functions impaired, in some tumors growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. When this nerve is paralyzed, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there are complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural, and by the ilio-inguinal. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralyzed alone, but occasionally in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacro-iliac disease: pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles.

Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The great sciatic nerve is liable to be pressed upon by various forms of pelvic tumors, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumors growing from the pelvic viscera, or bones, aneurisms of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of feces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to *sciatica*. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumors growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large (see page 785).

The sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured for the relief of *sciatica*. The nerve has also been stretched in cases of locomotor ataxy, the anæsthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line drawn from this to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Gluteus maximus is slightly nearer the tuber ischii than the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg.

The position of the external popliteal, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in subcutaneous division of the tendon. After it is divided, a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided.

THE SYMPATHETIC NERVE.

The Sympathetic Nervous System consists of (1) a series of ganglia, connected together by intervening cords, extending from the base of the skull to the coccyx, one on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller ganglia, situated in relation with the abdominal viscera; and (4) of numerous nerve-fibres. These latter are of two kinds: *communicating*, by which the ganglia communicate with each other and with the cerebro-spinal nerves: and *distributory*, supplying the internal viscera and the coats of the blood-vessels.

Each gangliated cord may be traced upward from the base of the skull into its cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery, and communicates with the ganglia on the first and second divisions of the fifth nerve. According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion (the *ganglion of Ribes*), situated upon the anterior communicating artery. The ganglia of these cords are distinguished as cervical, dorsal, lumbar, and sacral, and except in the neck they correspond pretty nearly in number to the vertebræ against which they lie. They may be thus arranged:

Cervical portion	.	.	3 pairs of ganglia.
Dorsal	"	.	12 " "
Lumbar	"	.	4 " "
Sacral	"	.	4 or 5 " "

In the neck they are situated in front of the transverse processes of the vertebræ; in the dorsal region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebræ; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion (*ganglion impar*) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebro-spinal nerves.

The branches of communication between the ganglia are composed of gray and white nerve-fibres, the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The branches of communication between the ganglia and the cerebro-spinal nerves also consist of white and gray nerve-fibres, which may be contained in separate filaments or united in a single branch; the former proceeding from the spinal nerve to the ganglion, the latter passing *from* the ganglion to the spinal nerve, so that a double interchange takes place between the two systems. While gray communicating fibres pass from all the sympathetic ganglia to all the spinal nerves, it would appear that the white communicating fibres from the spinal nerves to the sympathetic only exist in the dorsal and upper lumbar regions.

The **three great gangliated plexuses** are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the *cardiac*, the *solar* or *epigastric*, and the *hypogastric plexus*. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Smaller ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres.

The *branches of distribution* derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

THE GANGLIATED CORD.

Cervical Portion of the Gangliated Cord.

The cervical portion of the gangliated cord consists of three ganglia on each side, which are distinguished, according to their position, as the superior, middle, and inferior cervical.

The **Superior Cervical Ganglion**, the largest of the three, is placed opposite the second and third cervical vertebræ. It is of a reddish-gray color, and usually fusiform in shape, sometimes broad and flattened, and occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the *Rectus capitis anticus major* muscle.

Its branches may be divided into superior, inferior, external, internal, and anterior.

The *superior branch* appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The *outer branch*, the larger of the two, distributes filaments to the internal carotid artery and forms the *carotid plexus*.

The *inner branch* also distributes filaments to the internal carotid, and, continuing onward, forms the *cavernous plexus*.

FIG. 425.—The sympathetic nerve.

The Carotid Plexus.

The carotid plexus is situated on the outer side of the internal carotid. Filaments from this plexus occasionally form a small gangliform swelling on the under surface of the artery, which is called the carotid ganglion. The carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the sphenopalatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura mater (Valentin), while in the carotid canal it communicates with Jacobson's nerve, the tympanic branch of the glosso-pharyngeal.

The communicating branches with the sixth nerve consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the sphenopalatine ganglion is effected by a branch, the *large deep petrosal*, which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the great superficial petrosal to form the Vidian nerve. The Vidian nerve then proceeds along the pterygoid or Vidian canal to the sphenopalatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the *small deep petrosal nerve*, and the other the *carotico-tympanic*; the latter may consist of two or three delicate filaments.

The Cavernous Plexus.

The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella Turcica in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic ganglion, and distributes filaments to the wall of the internal carotid. The branch of communication with the third nerve joins it at its point of division; the branch to the fourth nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve.

The filament of connection with the ophthalmic ganglion arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine round the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinæ, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the *ganglion of Ribes*,¹ which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The inferior or descending branch of the superior cervical ganglion communicates with the middle cervical ganglion.

The external branches are numerous, and communicate with the cranial nerves and with the four upper spinal nerves. Sometimes the branch to the fourth spinal nerve may come from the cord connecting the upper and middle cervical ganglia. The branches of communication with the cranial nerves consist of delicate filaments, which pass from the superior cervical ganglion to the ganglion of the trunk of the pneumogastric and to the hypoglossal nerve. A separate filament from the cervical ganglion subdivides and joins the petrosal ganglion of the glosso-pharyngeal and the ganglion of the root of the pneumogastric in the jugular foramen.

The internal branches are three in number—the *pharyngeal*, *laryngeal*, and *superior cardiac nerve*. The *pharyngeal branches* pass inward to the side of the

¹ The existence of this ganglion is doubted by some observers.

FIG. 425.—Plan of the cervical portion of the sympathetic. (After Flower.)

pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the *pharyngeal plexus*. The *laryngeal branches* unite with the superior laryngeal nerve and its branches.

The *superior cardiac nerve* (*nervus superficialis cordis*) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the *Longus colli* muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve.

The *right superior cardiac nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the *arteria innominata*, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic: about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion.

The *left superior cardiac nerve*, in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The **anterior branches** ramify upon the external carotid artery and its branches, forming round each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external carotid is connected with the branch of the facial nerve to the *Stylo-hyoid* muscle; that surrounding the facial communicates with the submaxillary ganglion by one or two filaments; and that accompanying the middle meningeal artery sends offsets, which pass to the otic ganglion and to the geniculate ganglion of the facial nerve (external petrosal).

The **Middle Cervical Ganglion** (*thyroid ganglion*) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, "thyroid ganglion," assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

Its *superior branches* ascend to communicate with the superior cervical ganglion.

Its *inferior branches* descend to communicate with the inferior cervical ganglion.

Its *external branches* pass outward to join the fifth and sixth spinal nerves. These branches are not constantly found.

Its *internal branches* are the thyroid and the middle cardiac nerve.

The *thyroid branches* are small filaments which accompany the inferior thyroid artery to the thyroid gland; they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The *middle cardiac nerve* (*nervus cardiacus magnus*), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus.

The **Inferior Cervical Ganglion** is situated between the base of the transverse

process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves.

Its *superior branches* communicate with the middle cervical ganglion.

Its *inferior branches* descend, some in front of, others behind, the subclavian artery, to join the first thoracic ganglion.

Its *internal branch* is the inferior cardiac nerve.

The *inferior cardiac nerve* (*nervus cardiacus minor*) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

The *external branches* consist of several filaments, some of which communicate with the seventh and eighth spinal nerves; others accompany the vertebral artery along the vertebral canal, forming a plexus round the vessel, supplying it with filaments, which are continued up the vertebral and basilar to the cerebral arteries. The branches communicate with the cervical spinal nerves.

The Thoracic Portion of the Gangliated Cord.

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebræ, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs and covered by the pleura costalis; the last two are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebræ. The ganglia are small in size and of a grayish color. The first, larger than the rest, is of an elongated form and frequently blended with the last cervical. They are connected together by cord-like prolongations from their substance.

The *external branches* from each ganglion, usually two in number, communicate with each of the dorsal spinal nerves.

The *internal branches from the five or six upper ganglia* are very small; they supply filaments to the thoracic aorta and its branches, besides small branches to the bodies of the vertebræ and their ligaments. Branches from the third and fourth, and sometimes also from the first and second ganglia, form part of the posterior pulmonary plexus.

The *internal branches from the six or seven lower ganglia* are large and white in color; they distribute filaments to the aorta, and unite to form the three splanchnic nerves. These are named the *great*, the *lesser*, and the *smallest* or *renal splanchnic*.

The *great splanchnic nerve* is of a white color, firm in texture, and bears a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the fifth or sixth and the ninth or tenth, but the fibres in the higher roots may be traced upward in the sympathetic cord as far as the first or second thoracic ganglia. These roots unite to form a large round cord of considerable size. It descends obliquely inward in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the semilunar ganglion of the solar plexus, distributing filaments to the renal and suprarenal plexus.

The *lesser splanchnic nerve* is formed by filaments from the tenth and eleventh ganglia, and from the cord between them. It pierces the Diaphragm with the preceding nerve, and joins the solar plexus. It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The *smallest* or *renal splanchnic nerve* arises from the last ganglion, and,

piercing the Diaphragm, terminates in the renal plexus and lower part of the solar plexus. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the dorsal ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion of the Gangliated Cord.

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas muscle. It consists usually of four ganglia, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia.

The *superior* and *inferior branches of the lumbar ganglia* serve as communicating branches between the chain of ganglia in this region. They are usually single and of a white color.

The *external branches* communicate with the lumbar spinal nerves. From the situation of the lumbar ganglia these branches are longer than in the other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Of the *internal branches*, some pass inward, in front of the aorta, and help to form the aortic plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus. Numerous delicate filaments are also distributed to the bodies of the vertebræ and the ligaments connecting them.

Pelvic Portion of the Gangliated Cord.

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion (the *coccygeal ganglion* or *ganglion impar*).

The *superior* and *inferior branches* are the cords of communication between the ganglia above and below.

The *external branches*, exceedingly short, communicate with the sacral nerves. They are two in number from each ganglion. The coccygeal nerve communicates either with the last sacral or coccygeal ganglion.

The *internal branches* communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC.

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, above alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus.

The cardiac plexus is situated at the base of the heart, and is divided into a *superficial part*, which lies in the concavity of the arch of the aorta, and a *deep*

part, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The **great or deep cardiac plexus** (*plexus magnus profundus*, Scarpa) is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the inferior cervical cardiac branch from the left pneumogastric.

The branches from the *right side* of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form part of the posterior coronary plexus.

The branches from the *left side* of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the anterior pulmonary plexus, and then pass on to form the greater part of the posterior coronary plexus.

The **superficial (anterior) cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally the right) inferior cervical cardiac branches of the pneumogastric, and filaments from the deep cardiac plexus. A small ganglion (*cardiac ganglion of Wrisberg*) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus forms the chief part of the anterior coronary plexus, and several filaments pass along the pulmonary artery to the left anterior pulmonary plexus.

The **posterior or right coronary plexus** is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its filaments are distributed with those vessels to the muscular substance of the ventricles.

The **anterior or left coronary plexus** is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Epigastric or Solar Plexus (Figs. 425, 427).

The **Epigastric or Solar plexus** supplies all the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the stomach and in front of the aorta and crura of the Diaphragm. It surrounds the celiac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great and small splanchnic nerves of both sides, and some filaments from the right pneumogastric. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two **semilunar ganglia**, which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large irregular gangliform masses formed by the aggregation of smaller ganglia, having interspaces between them.

FIG. 427.—Lumbar portion of the gangliated cord, with the solar and hypogastric plexuses. (After Henle.)

They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following :

Phrenic or Diaphragmatic plexus.

Suprarenal plexus.

Renal plexus.

Spermatic plexus.

Coeliac plexus { Gastric plexus.
 Splenic plexus.
 Hepatic plexus.

Superior mesenteric plexus.

Aortic plexus.

The **phrenic plexus** accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion (*ganglion diaphragmaticum*). This ganglion is placed on the under surface of the Diaphragm, near the suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and hepatic plexus. There is no ganglion on the left side.

The **suprarenal plexus** is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

The **renal plexus** is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others to the spermatic plexus on both sides.

The **spermatic plexus** is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.

In the female the **ovarian plexus** is distributed to the ovaries and fundus of the uterus.

The **coeliac plexus**, of large size, is a direct continuation from the solar plexus: it surrounds the coeliac axis and subdivides into the gastric, hepatic, and splenic plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The **gastric or coronary plexus** accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The **hepatic plexus**, the largest offset from the coeliac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portæ.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a **pyloric plexus** accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a **gastro-duodenal plexus**, which subdivides into the pancreatico-duodenal plexus, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus; and a **gastro-epiploic plexus**, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach and anastomoses with branches from the splenic plexus. A **cystic plexus**, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The **splenic plexus** is formed by branches from the coeliac plexus, the left semilunar ganglia, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas (*pancreatic plexus*) and the left *gastro-epiploic*

plexus, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The **superior mesenteric plexus** is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the cœliac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. pancreatic branches to the pancreas; intestinal branches, which supply the whole of the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

The **aortic plexus** is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The *inferior mesenteric plexus* is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. the left colic and sigmoid plexuses, which supply the descending and sigmoid flexure of the colon; and the superior hæmorrhoidal plexus, which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus.

The **Hypogastric Plexus** supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the aortic plexus and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions, which form the *pelvic plexuses*.

The Pelvic Plexus.

The **pelvic plexus** (sometimes called *inferior hypogastric*) supplies the viscera of the pelvic cavity, is situated at the side of the rectum in the male, and at the side of the rectum and vagina in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The **inferior hæmorrhoidal plexus** arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior hæmorrhoidal plexus.

The **vesical plexus** arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesiculæ seminales and vas deferens; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **prostatic plexus** is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesiculæ seminales, and erectile structure of the penis. The nerves

supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the fore part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forward beneath the pubic arch.

The *small cavernous nerves* perforate the fibrous covering of the penis near its roots.

The *large cavernous nerve* passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpus cavernosum and spongiosum.

The **vaginal plexus** arises from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The **uterine plexus** arises from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the side of the organ between the layers of the broad ligament, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and Fallopian tube.

Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.

THE ORGANS OF SPECIAL SENSE.

THE Organs of the Senses are five in number, viz., those of Touch, of Taste, of Smell, of Hearing, and of Sight. The skin, which is the principal seat of the sense of touch, will be described in the section on General Anatomy. The remaining four are the Organs of Special Sense.

THE TONGUE.

The Tongue is the organ of the special sense of taste. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw.

Its base or root is directed backward, and connected with the os hyoides by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds (*glosso-epiglottic*) of mucous membrane; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictors and the mucous membrane. Its apex or tip, thin and narrow, is directed forward against the inner surface of the lower incisor teeth. The under surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles; from its sides the mucous membrane is reflected to the inner surface of the gums; and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the *frænum linguae*. To the outer side of the *frænum* is a slight fold of the mucous membrane, the *plica fimbriata*, the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.

The dorsum of the tongue is convex, marked along the middle line by a raphé, which divides it into symmetrical halves; this raphé terminates behind, about an inch from the base of the organ, in a depression, the *foramen cæcum*, from which a shallow groove, the *sulcus terminalis* of His, runs outward and forward on each side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, forming about two-thirds of its upper surface, is rough and covered with papillæ; the posterior third is smoother, and contains numerous muciparous glands and lymphoid follicles.

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions (page 325), containing much interposed fat, and supplied by vessels and nerves.

The **mucous membrane** invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the *frænum* through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes its papillary character.

The **structure of the mucous membrane of the tongue** differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in

structure with that lining the rest of the oral cavity. The mucous membrane covering the tongue behind the foramen cæcum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles, which together constitute what is sometimes termed the *lingual tonsil*. Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of mucous glands. The mucous membrane on the anterior part of the dorsum of the tongue is thin and intimately adherent to the

FIG. 428.—Upper surface of the tongue.

muscular tissue, and covered with minute eminences, the *papillæ* of the tongue. It consists of a layer of connective tissue, the *corium* or *mucosa*, supporting numerous *papillæ*, and covered, as well as the *papillæ*, with epithelium.

The epithelium is of the scaly variety, like that of the epidermis. It covers the free surface of the tongue, as may be easily demonstrated by maceration or boiling, when it can be easily detached entire: it is much thinner than on the skin: the intervals between the large *papillæ* are not filled up by it, but each *papilla* has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the *rete mucosum*, but they never contain coloring matter.

The *corium* consists of a dense feltwork of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

The Papillæ of the Tongue.—These are papillary projections of the corium. They are thickly distributed over the anterior two-thirds of its upper surface, giving to it its characteristic roughness. The varieties of papillæ met with are—the papillæ maximæ (*circumvallatæ*), papillæ mediæ (*fungiformes*), papillæ minimæ (*conicæ* or *filiformes*), and papillæ simplices.

FIG. 429.—The three kinds of papillæ, magnified.

The *papillæ maximæ* (*circumvallatæ*) are of large size, and vary from eight to twelve in number. They are situated at the back part of the dorsum of the tongue, near its base, forming a row on each side, which, running backward and inward, meet in the middle line, like the two lines of the letter V inverted. Each papilla consists of a projection of mucous membrane from $\frac{1}{10}$ to $\frac{1}{2}$ of an inch wide, attached to the bottom of a cup-shaped depression of the mucous membrane; the papilla is in shape like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting on the surface and being studded with numerous small secondary papillæ, which, however, are covered by a smooth layer of the epithelium. The cup-shaped depression forms a kind of fossa round the papilla, having a circular margin of about the same elevation covered with smaller papillæ.

Immediately behind the apex of the V is the foramen cæcum, mentioned above. This, according to His, represents the remains of the invagination which forms the median rudiment of the thyroid body, and for a time opens by a duct, the *thyroglossal duct*, on to the dorsum of the tongue. It may extend downward toward the hyoid bone. Kanthack, however, disputes this view.¹

The *papillæ mediæ* (*fungiformes*), more numerous than the preceding, are scattered irregularly and sparingly over the dorsum of the tongue, but are found chiefly at its sides and apex. They are easily recognized among the other papillæ, by their large size, rounded eminences, and deep-red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and covered with secondary papillæ. Their epithelial investment is very thin.

The *papillæ minimæ* (*conicæ* or *filiformes*) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papillæ *circumvallatæ*, excepting at the apex of the organ, where their direction

¹ *Journal of Anat. and Physiol.*, 1891.

is transverse. Projecting from their apices are numerous filiform processes or secondary papillæ; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

FIG. 430.—Circumvallate papillæ of tongue of rabbit, showing position of taste-goblets. (Stöhr.) a. Duct of gland. d. Serous gland. g. Taste-buds. l. Primary septa, and l', secondary septa, of papillæ. n. Medullated nerve. M. Muscular fibres.

which nerves are distributed in great abundance. If the epithelium is removed, it will be found that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillæ (Todd and Bowman). In the papillæ circumvallatæ the nerves are numerous and of large size; in the papillæ fungiformes they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillæ filiformes their mode of termination is uncertain. Buried in the epidermis of the papillæ circumvallatæ, and in some of the fungiformes, are certain peculiar bodies, called *taste-buds*.¹ They are flask-like in shape, their broad base resting on the corium, and their neck opening by an orifice, the *gustatory pore*, between the cells of the epithelium. They are formed by two kinds of cells; supporting cells and gustatory cells. The *supporting cells* are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The *gustatory cells* occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. The peripheral end of the cell terminates at the gustatory pore in a fine, hair-like filament, the *gustatory hair*. The central process passes toward the deep extremity of the bud, and there ends in a single or bifurcated varicose filament, which was formerly supposed to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve-fibrils after losing their medullary sheaths enter the taste-bud, and terminate in a fine extremity between the gustatory cells. Other nerve-fibrils may be seen ramifying between the cortical cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation, and not gustatory.

FIG. 431.—Taste-buds. a, Supporting cells. b, Gustatory cell.

¹ These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces, and also on the posterior surface of the epiglottis and anterior surface of the soft palate.

Glands of the Tongue.—The tongue is provided with mucous and serous glands.

The *mucous glands* are similar in structure to the labial and buccal glands. They are found especially at the back part, behind the circumvallate papillæ, but are also present at the apex and marginal parts. In connection with these glands a special one has been described by Blandin or Nuhn. It is situated near the apex of the tongue on either side of the frænum, and is covered over by a

FIG. 432.—Under surface of tongue, showing position and relations of gland of Blandin or Nuhn. (From a preparation in the Museum of the Royal College of Surgeons of England.)

fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis. It is from half an inch to nearly an inch long and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The *serous glands* occur only at the back of the tongue in the neighborhood of the taste-buds, their ducts opening for the most part into the fossæ of the circumvallate papillæ. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The *fibrous septum* consists of a vertical layer of fibrous tissue, extending throughout the entire length of the middle line of the tongue, from the base to the apex, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibro-cartilage about a quarter of an inch in length. It is well displayed by making a vertical section across the organ.

The **Hyo-glossal membrane** is a strong fibrous lamina which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genio-hyo-glossi.

Vessels of the Tongue.—The *arteries of the tongue* are derived from the lingual, the facial, and ascending pharyngeal. The *veins* open into the internal jugular.

Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic, which have already been described (page 325).

The *lymphatic vessels from the tongue* pass to one or two small glands situated

on the Hyo-glossus muscle in the submaxillary region, and thence to the deep glands of the neck.

The *nerves of the tongue* are five in number in each half: the lingual branch of the fifth, which is distributed to the papillæ at the fore part and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; the chorda tympani, which runs in the sheath of the lingual, is generally regarded as

FIG. 433.—Under surface of tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons of England.)

the nerve of taste for the same area; the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillæ circumvallatæ, and which supplies both sensory and gustatory filaments to this region; the hypo-glossal nerve, which is the motor nerve to the muscular substance of the tongue; and the superior laryngeal, which sends some fine branches to the root near to the epiglottis. Sympathetic filaments also pass to the tongue from the *nervi molles* on the lingual and other arteries supplying it.

Surgical Anatomy.—The diseases to which the tongue is liable are numerous, and its surgical anatomy of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of “tongue-tie,” from shortness of the frænum. (See page 489.)

There is, however, one condition which must be regarded as congenital, though it does not sometimes evidence itself until a year or two after birth, which is not uncommon. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the tongue. This is often

aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply-placed silver sutures. Compression has been resorted to in some cases and with success, but it is difficult to apply. Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to supuration and the formation of an acute abscess. Chronic abscess, which has been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms *leucoplakia*, *psoriasis*, and *ichthyosis* have been given.

The tongue, being very vascular, is often the seat of *nævroid* growths, and these have a tendency to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tubercle, syphilis, and cancer. Of these the cancerous ulcer is the most important, and probably also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated base. It produces great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from it to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to implication of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch is conducted to the tympanic plexus.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the *écraseur* or the scissors. Probably the better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the *Genio-hyo-glossus* first divided with a pair of curved blunt scissors. The *Palato-glossus* is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells's forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured hæmorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. In cases where the submaxillary glands are involved Kocher's operation should be performed. He removes the tongue from the neck, having performed a preliminary tracheotomy, by an incision from near the lobule of the ear, down the anterior border of the *Sterno-mastoid* to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth, pulled out through the external incision, and removed with the *écraseur* or knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawn through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the *Genio-hyo-glossi* detached from the bone, and the *Hyo-glossi* divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Any glands which are enlarged can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By the judicious use of iodoform this secondary evil may be obviated, and the preliminary tracheotomy is now usually dispensed with.

THE NOSE.

The nose is the peripheral organ of the sense of smell: by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food.

FIGS. 434, 435.—Cartilages of the nose.

The organ of smell consists of two parts: one external, the *outer nose*; the other internal, the *nasal fossæ*.

The *outer nose* (*nasus externus*) is the more anterior and prominent part of the organ of smell. Of a triangular form, it is directed downward, and projects from the centre of the face, immediately above the upper lip. Its summit, or *root*, is connected directly with the forehead. Its inferior part, or *base*, presents two elliptical orifices, the nostrils or anterior nares, separated from each other by an antero-posterior septum, the *columna*. The margins of these orifices are provided with a number of stiff hairs, or *vibrissæ*, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union in the middle line, the *dorsum*, the direction of which varies considerably in different individuals. The lateral surface terminates below in a rounded eminence, the *ala nasi*.

The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and supplied with vessels and nerves.

The *bony framework* occupies the upper part of the organ: it consists of the nasal bones and the nasal processes of the superior maxillary.

The *cartilaginous framework* consists of five pieces, the two upper and the two lower lateral cartilages and the cartilage of the septum.

The *upper lateral cartilages* are situated below the free margin of the nasal bones; each cartilage is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and continuous with the cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.

The *lower lateral cartilages* are two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of each orifice of the nostril. The portion which forms the inner wall, thicker than the rest, is loosely connected with the same part of the opposite cartilage, and forms a small part of the *columna*. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the *septum mobile*.

nasi. The part which forms the outer wall is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates (sesamoid cartilages—*cartilagines minores*). Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril; the ala being formed by dense cellular tissue covered by skin. In front the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

The *cartilage of the septum* is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossæ in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages. Below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the superior maxillary bones.

It may be prolonged backward (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the *processus sphenoidalis*. The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the inner portions of the lower lateral cartilages and by the skin; it is freely movable, and hence is termed the *septum mobile nasi*.

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The *muscles of the nose* are situated beneath the integument: they are (on each side) the *Pyramidalis nasi*, the *Levator labii superioris alæque nasi*, the *Dilatator naris*, anterior and posterior, the *Compressor nasi*, the *Compressor narium minor*, and the *depressor alæ nasi*. They have been described above (page 306).

The *integument* covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts: but where it forms the tip and the alæ of the nose it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The *mucous membrane* lining the interior of the nose is continuous with the skin externally and with that which lines the nasal fossæ within.

The *arteries of the nose* are the *lateralis nasi* from the facial, and the inferior artery of the septum from the superior coronary, which supply the alæ and septum, the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infra-orbital.

The *veins of the nose* terminate in the facial and ophthalmic.

The *nerves* for the muscles of the nose are derived from the facial, while the skin receives its branches from the infra-orbital, infratrochlear, and nasal branches of the ophthalmic.

FIG. 436.—Bones and cartilages of septum of nose. Right side.

Nasal Fossæ.

The nasal fossæ are two irregular cavities situated in the middle of the face, and extending from before backward. They open in front by the two anterior nares, and terminate, behind, by the posterior nares in the naso-pharynx. The *anterior nares* are somewhat pear-shaped apertures, each measuring about one inch antero-posteriorly and half an inch transversely at their widest part. The *posterior nares* are two oval openings, which are smaller in the living or recent subject than in the skeleton, because they are narrowed by the mucous membrane. Each measures an inch in the vertical, and half an inch in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossæ see section on Osteology.

Inside the aperture of the nostril is a slight dilatation, the *vestibule*, which extends as a small pouch, the *ventricle*, toward the point of the nose. The fossa, above and behind the vestibule, has been divided into two parts: an *olfactory* portion, consisting of the upper and central part of the septum and probably the superior turbinated bone, and a *respiratory* portion, which comprises the rest of the fossa.

Outer Wall.—The sphenoidal air sinus opens into the *spheno-ethmoidal recess*, a narrow recess above the superior turbinated bone. The posterior ethmoidal cells open into the front and upper part of the superior meatus. On raising or cutting away the middle turbinated bone the outer wall of the middle meatus is fully exposed, and presents (1) a rounded elevation, termed the *bullæ ethmoidalis*, opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a deep, narrow, curved groove, in front of the bullæ ethmoidalis, termed the *hiatus semilunaris*, into which the anterior ethmoidal cells and the antrum of Highmore open, the orifice of the latter being placed near the level of its roof. The middle meatus is prolonged, above and in front, into the *infundibulum*, which leads into the frontal sinus. The anterior extremity of the meatus is continued into a depressed area, which lies above the vestibule and is named the *atrium*. The *nasal duct* opens into the anterior part of the inferior meatus, the opening being frequently overlapped by a fold of mucous membrane.

The inner wall or septum is frequently more or less deflected from the mesial plane, thus limiting the size of one fossa and increasing that of the other. Ridges or spurs of bone growing outward from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the *naso-palatine recess*, may be seen. In the septum close to this recess a minute orifice may be discerned: it leads into a blind pouch, the rudimentary *organ of Jacobson*, which is well developed in some of the lower animals, and is supported by a plate of cartilage, the *cartilage of Jacobson*.

The *mucous membrane* lining the nasal fossæ is called the *pituitary*, from the nature of its secretion; or *Schneiderian*, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the periosteum or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the naso-pharynx through the posterior nares. From the nasal fossæ its continuity may be traced with the conjunctiva through the nasal duct and lachrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossæ it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossæ are much

narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstance also the various apertures communicating with the meatuses are considerably narrowed or completely closed.

The vestibule is lined by modified skin, and contains hairs or vibrissæ which guard the entrance of the nostril.

Structure of the Mucous Membrane.—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the respiratory portion of the nasal cavity the epithelium is columnar and ciliated. Interspersed among the columnar ciliated cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. In this region, beneath the epithelium and its basement membrane, is a fibrous

FIG. 437.—Transverse vertical section of the nasal fossæ. The section is made anterior to the superior turbinated bones. (Cryer.)

layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the olfactory region the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells. The *supporting cells* contain oval nuclei, situated in the deeper parts of the cells: the free surface of each cell presents a sharp outline, and its deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the supporting cells are a large number of spindle-shaped cells, the *olfactory cells*, which consist of a large spherical nucleus surrounded by a small

amount of granular protoplasm, and possessing two processes, of which one runs outward between the columnar epithelial cells, and projects on the surface of the

FIG. 438.—Section of the olfactory mucous membrane. (Cadiat.) a. Epithelium. b. Glands of Bowman. c. Nerve bundles.

mucous membrane as a fine, hair-like process, the *olfactory hair*; the other or deep process runs inward, is frequently

beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the *glands of Bowman*, identical in structure with serous glands.

FIG. 439.—Nerves of septum of nose. Right side.

which supply the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The *veins of the nasal fossæ* form a close, cavernous-like network beneath the mucous membrane. This cavernous appearance is especially well marked over the lower part of the septum and over the middle and inferior turbinated bones. Some of the veins pass, with those accompanying the sphenopalatine artery, through the sphenopalatine foramen; and others, through the alveolar branch, to join the facial vein; some accompany the ethmoidal arteries, and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the

The *arteries of the nasal fossæ* are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the sphenopalatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the inferior artery of the septum, from the superior coronary of the facial; and the infraorbital and alveolar branches of the internal maxillary,

skull, through the foramina in the cribriform plate of the ethmoid bone, and the foramen cæcum.

The *lymphatics* can be injected from the subdural and subarachnoid spaces, and form a plexus in the superficial portion of the mucous membrane. The lymph is drained partly into one or two glands which lie near the great cornu of the hyoid bone and partly into a gland situated in front of the axis.

The *nerves* are: the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the nasopalatine, descending anterior palatine, and nasal branches of Meckel's ganglion.

The *olfactory*, the special nerve of the sense of smell, is distributed to the olfactory region, already referred to (page 820).

The *nasal branch of the ophthalmic* distributes filaments to the fore part of the septum and outer wall of the nasal fossæ.

Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinated bone.

The *Vidian nerve* supplies the upper and back part of the septum and superior spongy bone, and the *upper anterior nasal branches* from the sphenopalatine ganglion have a similar distribution.

The *naso-palatine nerve* supplies the middle of the septum.

The *larger or anterior palatine nerve* supplies the *lower nasal branches* to the middle and lower spongy bones.

Surgical Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis, or imperfect development of the nasal bones in cases of congenital syphilis, or a lateral deviation of the nose may result from fracture.

The skin over the alæ and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. It is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term "grog-blossom" is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed *lipomata nasi*. Epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. It can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Rouge's operation, which was introduced for the cure of ozæna by the removal of any dead bone which may be present in this disease. The whole framework of the nose is lifted up by an incision made inside the mouth, through the junction of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line; this may be the result of an injury or from some congenital defect in its development; in the latter case the deviation usually occurs along the line of union of the vomer and mesethmoid, and rarely occurs before the seventh year. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossæ, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection and may arise from several causes: syphilitic or tubercular ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hæmorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypus is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. Their most common seat is probably the middle turbinated bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossæ. The malignant polypi, both sarcomatous or carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths, or nose-stones, may sometimes be found in the nasal cavities, from the formation of phosphate of lime upon either a foreign body or a piece of inspissated secretion.

THE EYE.

The eyeball is contained in the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to different parts; it is supplied by vessels and nerves, and is additionally protected in front by several appendages, such as the eyebrow, eyelids, etc.

The eyeball is imbedded in the fat of the orbit, but is surrounded by a thin membranous sac, the *capsule of Tenon*, which isolates it, so as to allow of free movement.

The *capsule of Tenon* consists of a thin membrane which envelops the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is in contact with the outer surface of the sclerotic, the *perisclerotic lymph-space* only intervening. This lymph-space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of connective tissue which extend between the capsule and the sclerotic. The capsule is perforated behind by the ciliary vessels and nerves and by the optic nerve, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the muscles which move the eyeball and on each it sends a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous pulley of that muscle; that on the Inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebræ; that of the Inferior rectus is attached to the inferior tarsal plate. These two recti, therefore, will exercise some influence on the movements of the eyelids. The expansions from the sheaths of the Internal and External recti are strong, especially the one from the latter muscle, and are attached to the lachrymal and malar bones respectively. As they probably check the action of these two recti, they have been named the *internal* and *external check ligaments*.

Lockwood has also described a thickening of the lower part of the capsule of Tenon, which he has named the *suspensory ligament of the eye*. It is slung like a hammock below the eyeball, being expanded in the centre and narrow at its extremities, which are attached to the malar and lachrymal bones respectively.¹

The eyeball is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the posterior segment, which is one of a much larger sphere, and forms about five-sixths of the globe. The segment of the larger sphere

¹ See a paper by C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx., part i., p. 1.

is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the smaller sphere is transparent, and formed by the cornea. The term *anterior pole* is applied to the central point of the anterior curvature of the eyeball, and that of *posterior pole* to the central point of its posterior curvature; a line joining the two poles forms its *sagittal axis*. The axes of the eyeballs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed outward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each enters its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole. The eyeball measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to nearly an inch, the latter to about nine-tenths of an inch.

The eyeball is composed of three investing tunics and of three refracting media.

TUNICS OF THE EYE.

From without inward the three tunics are:

1. Sclerotic and Cornea.
2. Choroid, Ciliary Body, and Iris.
3. Retina.

I. The Sclerotic and Cornea.

The sclerotic and cornea (Fig. 440) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclerotic being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, being transparent.

The Sclerotic (*σκληρός*, *hard*) has received its name from its extreme density and hardness; it is a firm, unyielding, fibrous membrane, serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white color, and is in contact with the inner surface of the capsule of Tenon; it is quite smooth, except at the points where the Recti and Obliqui muscles are inserted into it, and its anterior part is covered by the conjunctival membrane: hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained of a brown color, marked by grooves, in which are lodged the ciliary nerves and vessels; this is loosely connected by an exceedingly fine cellular tissue (*lamina fusca*) with the outer surface of the choroid, an extensive lymph-space (*perichoroidal*) intervening between the sclerotic and choroid. Behind it is pierced by the optic nerve, and is continuous with its fibrous sheath, which is derived from the dura mater. At the point where the optic nerve passes through the sclerotic, this tunic forms a thin cribriform lamina (the *lamina cribrosa*); the minute orifices in this region serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve-fibres. One of these openings, larger than the rest, occupies the centre of the lamella; it transmits the arteria centralis retinae to the interior of the eyeball. Around the cribriform lamella are numerous small apertures for the transmission of the ciliary vessels and nerves, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of veins (*venae vorticosae*). In front, the fibrous tissue of the sclerotic is directly continuous with that of the cornea by direct continuity of tissue, but the opaque sclerotic slightly overlaps the outer surface of the transparent cornea.

Structure.—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres. These fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. It yields gelatin on boiling. Its vessels are not numerous, the capillaries being of small size, uniting at long and wide intervals. Its nerves are derived from the ciliary nerves, but their exact mode of ending is not known.

The **Cornea** is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from its case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic.

Structure.—The cornea consists of four layers—namely, (1) several strata of epithelial cells, continuous with those of the conjunctiva; (2) a thick central

FIG. 440.—A horizontal section of the eyeball. (Allen.)

fibrous structure, the *substantia propria*; (3) a homogeneous elastic lamina; and (4) a single layer of endothelial cells forming part of the lining membrane of the anterior chamber of the eyeball.

The *conjunctival epithelium*, which covers the front of the cornea proper, consists of several strata of epithelial cells. The deepest layers are columnar: then follow two or three layers of polyhedral cells, the majority of which present finger-like processes (*i. e.*, prickles), similar to those found in the cuticle. Lastly, there are three or four layers of scaly epithelium with flattened nuclei.

The *proper substance of the cornea* is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellæ at right angles to each other. Fibres, however, frequently pass from one lamella to the next.

The lamellæ are connected with each other by an interstitial cement-substance,

in which are spaces, the *corneal spaces*. The spaces are stellate in shape, and have numerous offsets by which they communicate with each other. Each contains a cell, the *corneal corpuscle*, which resembles in form the space in which it is lodged, but it does not entirely fill it.

Immediately beneath the conjunctival epithelium the cornea proper presents certain characteristics which have led some anatomists to regard it as a distinct membrane, and it has been named by Bowman the *anterior elastic lamina*. It differs, however, from the true elastic lamina or membrane of Descemet in many essential particulars, presenting evidence of fibrillar structure, and not having the same tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It ought, therefore, to be regarded as a part of the proper tissue of the cornea.¹

The *posterior elastic lamina* (*membrane of Descemet or Demours*), which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of an elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up, or roll upon itself, with the attached surface innermost, when separated from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) "to preserve the requisite permanent correct curvature of the flaccid cornea proper."

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the *spaces of Fontana*. These little recesses communicate with a circular canal in the substance of the sclerotic close to its junction with the cornea. This is the *canal of Schlemm*, or *sinus venosus scleræ*; it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the *ligamentum pectinatum iridis*; while others are connected with the fore part of the sclerotic and choroid.

The *endothelial lining of the aqueous chamber* covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of Fontana. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those lining other serous cavities.

Arteries and Nerves.—The cornea is a non-vascular structure, the capillary vessels terminating in loops at its circumference. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these are lined by an endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in number (Kölliker), forty to forty-five (Waldeyer and Sümisch); they are derived from the ciliary nerves and enter the laminated tissue of the cornea. They ramify throughout its substance in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper beneath the epithelium. This is termed the *subepithelial plexus*, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the *intra-epithelial plexus*.

Dissection.—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity

¹ This layer has been called by Reichert the "anterior limiting layer"—a name which appears more applicable to it than that of "anterior elastic lamina."

of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves may be seen lying in the loose cellular tissue between the choroid and sclerotic or continued in delicate grooves on the inner surface of the latter membrane.

II. The Choroid, Ciliary Body, and Iris.

The Second Tunic of the Eye (*tunica vasculosa oculi*) is formed from behind forward by the choroid, the ciliary body, and the iris.

The choroid is the vascular and pigmentary tunic of the eyeball, investing the posterior five-sixths of the globe, and extending as far forward as the ora serrata of the retina; the ciliary body connects the choroid to the circumference of the iris. The iris is the circular muscular septum, which hangs vertically behind the cornea, presenting in its centre a large rounded aperture, the *pupil*.

The **Choroid** is a thin, highly vascular membrane, of a dark-brown or chocolate color, which invests the posterior five-sixths of the globe, and is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclerotic. It is thicker behind than in front. Externally, it is loosely connected by the lamina fusca with the inner surface of the sclerotic. Its inner surface is attached to the retina.

FIG. 441.—The choroid and iris. (Enlarged.)

Structure.—The choroid consists mainly of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus. On its external surface—*i. e.*, the surface next the sclerotic—is a thin membrane, the *lamina superchoroidea*, composed of delicate non-vascular lamellæ, each lamella consisting of a network of fine elastic fibres, among which are branched pigment-cells. The spaces between the lamellæ are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the perisclerotic space by the perforations in the sclerotic through which the vessels and nerves are transmitted.

Internal to this is the *choroid proper*, and, in consequence of the small arteries and veins being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers: the outermost, composed of small arteries and veins, with pigment-cells interspersed between them, and the inner, consisting of a capillary plexus. The *external layer* or *lamina vasculosa*

consists, in part, of the larger branches of the short ciliary arteries which run forward between the veins, before they bend inward to terminate in the capillaries; but is formed principally of veins, which are named, from their arrangement, *venæ vorticosa*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Interspersed between the vessels are dark star-shaped pigment-cells, the offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary character. The *internal layer* consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels, and is known as the *lamina chorio-capillaris* or *tunica Ruyschiana*. The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous with those of the ciliary processes.

FIG. 442.—The veins of the choroid. (Enlarged.)

These two laminæ are connected by an *intermediate stratum*, which is destitute of pigment-cells and consists of fine elastic fibres. On the inner surface of the lamina chorio-capillaris is a very thin, structureless, or, according to Kölliker, faintly fibrous membrane, called the *lamina basalis* or membrane of Bruch; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

Tapetum.—This name is applied to the iridescent appearance which is seen in the outer and posterior part of the choroid of many animals.

The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining it from behind.

The **ciliary body** comprises the orbiculus ciliaris, the ciliary processes, and the Ciliary muscle.

The *orbiculus ciliaris* is a zone of about one-sixth of an inch in width, directly continuous with the anterior part of the choroid; it presents numerous ridges arranged in a radial manner.

The *ciliary processes* are formed by the plaiting and folding inward of the various layers of the choroid—i. e., the choroid proper and the lamina basalis—at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill behind the iris, round the margin of the lens. They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces

between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid: the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are covered on their inner surface by two strata of black pigment-cells, which are continued forward from the retina, and are named the *pars ciliaris retinæ*. In the stroma of the ciliary processes there are also stellate pigment-cells, which, however, are not so numerous as in the choroid itself.

FIG. 443.—The arteries of the choroid and iris. The sclerotic has been mostly removed. (Enlarged.)

The *Ciliary muscle* (Bowman) consists of unstriped fibres: it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the fore part of the choroid. It is thickest in front, and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular. The former, much the more numerous, arise at the point of junction of the cornea and sclerotic, and partly also from the ligamentum pectinatum iridis, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic. The circular fibres are internal to the radiating ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the “ring muscle” of Müller, and were formerly described as the ciliary ligament. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes. The Ciliary muscle is admitted to be the chief agent in accommodation,—i. e., in adjusting the eye to the vision of near objects. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance; but the view which now prevails is that the contraction of the muscle, by drawing on the ciliary processes, relaxes the suspensory ligament of the lens, thus allowing the anterior surface of the lens to become more convex. The pupil is at the same time slightly contracted.¹

The *Iris* (*iris*, a rainbow) has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in

¹ See explanation and diagram in Power's *Illustrations of some of the Principal Diseases of the Eye*, p. 590.

the aqueous humor behind the cornea, and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the *pupil*, for the transmission of light. By its circumference it is continuous with the ciliary body, and is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament; its inner or free edge forms the margin of the pupil; its surfaces are flattened, and look forward and backward, the anterior toward the cornea, the posterior toward the ciliary processes and lens. The anterior surface of the iris is variously colored in different individuals, and marked by lines which converge toward the pupil. The posterior surface is of a deep purple tint, from being covered by two layers of pigmented, columnar epithelium, which are continuous posteriorly with the *pars ciliaris retinæ*. This pigmented epithelium is termed the *pars iridica retinæ*, though it is sometimes named *uvea*, from its resemblance in color to a ripe grape.

FIG. 444.—Section of the eye, showing the relations of the cornea, sclerotic, and iris, together with the Ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement-membrane. This layer is continuous with the epithelial layer covering the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. *Stroma.*—The stroma consists of fibres and cells. The former are made of fine, delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The *muscular fibre* is involuntary, and consists of circular and radiating fibres. The *circular fibres* (sphincter pupillæ) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width, those near the free margin being closely aggre-

gated; those more external somewhat separated, and forming less complete circles. The *radiating fibres* (dilator pupillæ) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular.

4. *Pigment*.—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface of the iris and continuous with the pigmentary lining of the ciliary processes. The color of the eye in these individuals is due to this coloring-matter showing more or less through the texture of the iris. In the albino even this pigment is absent. In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the epithelial layer on the front of the iris; to these the dark color of the eye is due.

The *arteries of the iris* are derived from the long and anterior ciliary and from the vessels of the ciliary processes (see page 509). The long ciliary arteries, two in number, having reached the attached margin of the iris, divide into an upper and a lower branch, and, encircling the iris, anastomose with corresponding branches from the opposite side; into this vascular zone (circulus major) the anterior ciliary pour their blood. From this zone vessels converge to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (circulus minor) in this situation.

The *nerves of the choroid and iris* are derived from the ciliary branches of the lenticular ganglion, and the long ciliary from the nasal branch of the ophthalmic division of the fifth. They pierce the sclerotic around the entrance of the optic nerve, and run forward in the perichoroidal space, and supply the blood-vessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived non-medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the fœtus the pupil is closed by a delicate transparent vascular membrane, the *membrana pupillaris*, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by its gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

III. The Retina.

The *Retina* is a delicate nervous membrane, upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward; and, in front, extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the *ora serrata*. Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the *pars ciliaris retinæ* and *pars iridica retinæ*, already referred to. This forward prolongation consists of the pigmentary layer of the retina together with a stratum of columnar epithelium. The retina is soft, semi-transparent, and of a purple tint in the fresh state, owing to the presence of a coloring-material named *rhodopsin* or *visual purple*; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the

posterior part of the retina, corresponding to the axis of the eye, and at a point in which the sense of vision is most perfect, is an oval yellowish spot, called, after its discoverer, the *yellow spot* or *macula lutea* of Sommerring, having a central depression, the *fovea centralis*. The retina in the situation of the fovea centralis is exceedingly thin, and the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name "foramen of Sommerring" at first given to it. It exists only in man, the quadrumana, and some saurian reptiles. About one-eighth of an inch (3 mm.) to the inner side of the yellow spot is the point of entrance of the optic nerve (*porus opticus*); here the nervous substance is slightly raised so as to form an eminence (*colliculus nervi optici*); the arteria centralis retinæ pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the "blind spot."

Structure.—The retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of ten layers, which are named from within outward, as follows:

1. Membrana limitans interna.
2. Layer of nerve-fibres (stratum opticum).
3. Ganglionic layer, consisting of nerve-cells.
4. Inner molecular, or plexiform, layer.
5. Inner nuclear layer, or layer of inner granules.
6. Outer molecular, or plexiform, layer.
7. Outer nuclear layer, or layer of outer granules.
8. Membrana limitans externa.
9. Jacob's membrane (layer of rods and cones).
10. Pigmentary layer (tapetum nigrum).

1. The *membrana limitans interna* is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

2. The *layer of nerve-fibres* is formed by the expansion of the optic nerve. This nerve passes through all the other layers of the retina, except the *membrana*

FIG. 445.—The arteria centralis retinæ, yellow spot, etc., the anterior half of the eyeball being removed. (Enlarged.)

limitans interna, to reach its destination. As the nerve passes through the lamina cribrosa of the sclerotic coat, the fibres of which it is composed lose their medullary sheaths and are continued onward, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the

retina, they radiate from their point of entrance over the surface of the retina, grouped in bundles, and in many places, according to Michel, arranged in plexuses. Most of the fibres in this layer are ventripetal, and are the direct continuations of the axis-cylinder processes of the cells of the next layer, but a few of them (centrifugal fibres) pass through it and the next succeeding layer to ramify in the inner molecular and inner nuclear layers, where they terminate in enlarged extremities (Fig. 448, 1, *m*). The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The *ganglionic layer* consists of a single layer of large ganglion-cells; except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, their rounded internal margin resting on the preceding layer

FIG. 446 and 447.—Vertical sections of the human retina. Fig. 446, half an inch from the entrance of the optic nerve. Fig. 447, close to the latter. 1. Layer of rods and cones, Jacob's membrane, bounded underneath by the *membrana limitans externa*. 2. Outer nuclear layer. 3. Outer molecular layer. 4. Inner nuclear layer. 5. and sending off an axon which is prolonged as a nerve-fibre into the fibrous layer. From the opposite extremity numerous thicker processes (dendrites) extend into the inner molecular layer, where they branch out into flattened arborizations at different levels (Fig. 448, VII). The ganglion-cells vary much in size, and the dendrites of the smaller ones as a rule arborize in the inner molecular layer as soon as they enter it; while the processes of the larger cells ramify close to the inner nuclear layer.

4. The *inner molecular layer* is made up of a dense reticulum of minute fibrils, formed by the interlacement of the dendrites of the ganglion-cells with those of the cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibrils a few branched spongioblasts are sometimes imbedded.

5. The *inner nuclear layer* is made up of a number of closely packed cells, of which there are three different kinds. (1) A large number of oval cells, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They each consist of a large oval body placed vertically to the surface, and containing a distinct nucleus: they are surrounded by a small amount of protoplasm, which is prolonged into two processes: one of these passes inward into the inner molecular layer, is varicose in appearance, and ends in a terminal ramification, which is often in close proximity to the ganglion-cells (Fig. 448 1, *c*).

The outer process passes outward into the outer molecular layer, and there breaks up into a number of branches. According to Cajal, there are two varieties of these bipolar cells: one in which the outer process arborizes around the knobbed ends of the rod-fibres, and the inner around the cells of the ganglionic layer; these he calls *rod-bipolars* (Fig. 448, 1, c, d); the others are those in which the outer process breaks up in a horizontal ramification, in contact with the end of a cone-fibre; these are the *cone-bipolars*, and their inner process breaks up into its terminal ramifications in the inner molecular layer (Fig. 448, 1, e). (2) At the innermost part of this inner nuclear layer is a stratum of cells, which are named by Cajal *amacrine* cells, from the fact that they have no axis-cylinder process, but they give a number of short protoplasmic processes which extend into the inner molecular layer and there ramify (Fig. 448, 1, h). There are also at the outermost part of this layer some cells, the processes of which extend into and ramify in the outer molecular layer. These are the *horizontal* cells of Cajal. (3) Some few cells are also found in this layer, connected with the fibres of Müller, and will be described with those structures.

6. The *outer molecular layer* is much thinner than the inner molecular layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the horizontal cells of the preceding layer and the outer processes of the bipolar cells, which ramify in it, forming arborizations around the ends of the rod-fibres and with the branched foot-plates of the cone-fibres.

7. *The Outer Nuclear Layer.*—Like the inner nuclear layer, this layer contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane are named *rod-granules* and *cone-granules*. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of the granule is a fine process: the outer process is continuous with a single rod of Jacob's membrane; the inner passes inward toward the outer molecular layer and terminates in an enlarged extremity, and is embedded in the tuft into which the outer process of the rod-bipolars break up. In its course it presents numerous varicosities. The *cone-granules*, fewer in number than the rod-granules, are placed close to the *membrana limitans externa*, through which they are continuous with the cones of Jacob's membrane. They do not present any cross-striping, but contain a pyriform nucleus which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, upon which it rests by a somewhat pyramidal enlargement, from which are given off numerous fine fibrils, which enter the outer molecular layer, where they come in contact with the outer processes of the cone-bipolars.

8. *The Membrana Limitans Externa.*—This layer, like the *membrana limitans interna*, is derived from the fibres of Müller, with which structures it will be described.

9. *Jacob's Membrane (Layer of Rods and Cones).*—The elements which compose this layer are of two kinds, *rods* and *cones*, the former being much more numerous than the latter. The *rods* are of nearly uniform size, and arranged perpendicularly to the surface. Each rod consists of two portions, an outer and inner, which are of about equal length. The segments differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained with these reagents, but staining yellowish brown with osmic acid. The outer portion of each rod is marked by transverse striæ, and is made up of a number of thin disks superimposed on one another. It also exhibits faint longitudinal markings. The inner portion of each rod, at its deeper part where it is joined to the outer process of the rod-granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibrils. The visual purple or rhodopsin is found only in the outer segments of the rods.

FIG. 448.—Elements of the retina of mammals, displayed by the chromate of silver method of Golgi. (Cajal.) (Copied from Quain's *Anatomy*.)

The *cones* are conical or flask-shaped, their broad ends resting upon the *membrana limitans externa*, the narrow pointed extremity being turned to the choroid. Like the rods, they are made up of two portions, outer and inner; the outer portion is a short conical process, which, like the outer segment of the rods, presents transverse striæ. The inner portion resembles the inner portion of the rods in structure, presenting a superficial striated and deeper granular part; but differs from it in size, being bulged out laterally and presenting a flask shape. The chemical and optical characters of the two portions are identical with those of the rods.

10. *The Pigmentary Layer, or Tapetum Nigrum*.—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment-granules. They are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. In the eyes of albinos, the cells of the pigmentary layer are present, but they contain no coloring-matter. In many of the mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the *tapetum lucidum*.

Supporting Framework of the Retina.—Almost all these layers of the retina are connected together by a supporting framework, formed by the *fibres of Müller*, or *radiating fibres*, from which the *membrana limitans interna et externa* are derived. These fibres are found stretched between the two limiting layers, "as columns between a floor and a ceiling," and passing through all the nervous layers except Jacob's membrane. Each commences on the inner surface of the retina by a conical hollow base, which sometimes contains a spheroidal body, stained deeply with hæmatoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the *membrana limitans interna*. As they pass through the nerve-fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network around the rod and cone-fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre.

DESCRIPTION OF FIG. 448.

- I. Section of the dog's retina. *a*, Cone-fibre. *b*, Rod-fibre and nucleus. *e, d*, Bipolar cells (inner granules) with vertical ramification of outer processes destined to receive the enlarged ends of rod-fibres. *e*, Bipolars with flattened ramification for ends of cone-fibres. *f*, Giant bipolar with flattened ramification. *g*, Cell sending a neuron or nerve-fibre process to the outer molecular layer. *h*, Amacrine cell with diffuse arborization in inner molecular layer. *i*, Nerve-fibrils passing to outer molecular layer. *j*, Centrifugal fibres passing from nerve-fibre layer to inner molecular layer. *m*, Nerve-fibril passing into inner molecular layer. *n*, Ganglionic cells.
- II. Horizontal or basal cells of the outer molecular layer of the dog's retina. *A*, Small cell with dense arborization. *B*, Large cell, lying in inner nuclear layer, but with its processes branching in the outer molecular. *a*, Its horizontal neuron. *c*, Medium-sized cell of the same character.
- III. Cells from the retina of the ox. *a*, Rod-bipolars with vertical arborizations. *b, c, d, e*, Cone-bipolars with lateral and ramification of outer process. *h*, Cells lying on the outer surface of the outer molecular layer, and ramifying within it. *i, j, m*, Amacrine cells within the substance of the inner molecular layer.
- IV. Neurons or axis-cylinder processes belonging to horizontal cells of the outer molecular layer, one of them, *b*, ending in a close ramification at *a*.
- V. Nervous elements connected with the inner molecular layer of the ox's retina. *A*, Amacrine cell, with long processes ramifying in the outermost stratum. *B*, Large amacrine with thick processes ramifying in second stratum. *C*, Flattened amacrine with long and fine processes ramifying mainly in the first and fifth strata. *D*, Amacrine with radiating tuft of fibrils destined for third stratum. *E*, Large amacrine with processes ramifying in fifth stratum. *F*, Small amacrine, branching into second stratum. *G, H*, Other amacrine cells destined for fourth stratum. *a*, Small ganglion-cell sending its processes to fourth stratum. *b*, A small ganglion-cell with ramifications in three strata. *c*, A small cell ramifying ultimately in first stratum. *d*, A medium-sized ganglion-cell ramifying in fourth stratum. *e*, Giant-cell, branching in third stratum. *f*, A bistratified cell ramifying in second and fourth strata.
- VI. Amacrine and ganglion-cells from the dog. *A*, Amacrine with radiating tuft. *B*, Large amacrine passing to third stratum. *C* and *G*, Small amacrine with radiations in second stratum. *F*, Small amacrine passing to third stratum. *D*, Amacrine with diffuse arborization. *E*, Amacrine belonging to fourth stratum. *a, d, e, g*, Small ganglion-cells, ramifying in various strata. *b, f*, Large ganglion-cells showing two different characters of arborization. *i*, Bistratified cell.
- VII. Amacrine and ganglion-cells from the dog. *A, B, C*, Small amacrine ramifying in middle of molecular layer. *b, d, g, h, i*, Small ganglion-cells showing various kinds of arborization. *f*, A larger cell, similar in character to *g*, but with longer branch. *a, c, e*, Giant-cells with thick branches ramifying in the first, second, and third layers. *L, L*, Ends of bipolars branching over ganglion-cells.

Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are

FIG. 449.—The layers of the retina (diagrammatic). (After Schultze.)

wanting as a continuous layer ; (2) the ganglionic layer consists of several strata of cells, instead of a single layer ; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts ; and (4) in the outer nuclear layer there are only cone fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer, the pigmentary layer, which is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except Jacob's membrane ; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the *ora serrata* the nervous layers of the retina terminate abruptly, and the retina is continued onward as a single layer of elongated columnar cells covered by the pigmentary layer. This prolongation is known as the *pars ciliaris retinae*, and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the *pars iridica retinae* or *uvea*.

From the description given of the nervous elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve-fibre layers, the majority of the nerve-fibres being formed of the axons of the ganglionic cells. In the inner molecular layer the dendrites of the ganglionic layer interlace with those of the cells of the inner nuclear layer, while in the outer molecular layer a like

synapsis occurs between the processes of the inner granules and the rod and cone elements.

The *arteria centralis retinæ* and its accompanying vein pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately bifurcates into an upper and a lower branch, and each of these again divides into an inner, or nasal, and an outer, or temporal, branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the *arteria centralis retinæ* do not anastomose with each other—in other words, they are “terminal arteries.” In the foetus, a small vessel passes forward, through the vitreous humor, to the posterior surface of the capsule of the lens.

REFRACTING MEDIA.

The Refracting media are three, viz.:

Aqueous humor.

Vitreous body.

Crystalline lens.

I. Aqueous Humor.

The aqueous humor completely fills the anterior and posterior chambers of the eyeball. It is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

The *anterior chamber* is the space bounded in front by the cornea; behind, by the front of the iris. The *posterior chamber* is a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens, and the ciliary processes.

In the adult, these two chambers communicate through the pupil; but in the foetus of the seventh month, when the pupil is closed by the *membrana pupillaris*, the two chambers are quite separate.

II. Vitreous Body.

The vitreous body forms about four-fifths of the entire globe. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the *fossa patellaris*, for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the *membrana hyaloidea*. It has been supposed by Hannover, that from its inner surface numerous thin lamellæ are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellæ cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body; and in the foetus a peculiar fibrous texture pervades the mass, the fibres joining at numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the *canal of Stilling*, which in the embryonic vitreous humor conveyed the minute vessel from the central artery of the retina to the back of the lens. The fluid from the vitreous body resembles nearly pure water; it contains, however, some salts and a little albumin.

The hyaloid membrane encloses the whole of the vitreous humor. In front of the *ora serrata* it is thickened by the accession of radial fibres and is termed

the *zonule of Zinn* or *zonula ciliaris*. It presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they are adherent, as evidenced by the fact that when removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two layers, one of which is thin and lines the fossa patellaris; the other is named the *suspensory ligament of the lens*; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, the *canal of Petit*, which encircles the equator of the lens and which can be easily inflated through a fine blow-pipe inserted through the suspensory ligament.

In the *fœtus*, the centre of the vitreous humor presents the canal of Stilling, already referred to, which transmits a minute artery to the capsule of the lens. In the *adult*, no vessels penetrate its substance; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. Crystalline Lens.

The **crystalline lens**, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and encircled by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens. It rests, behind, in the fossa patellaris in the fore part of the vitreous body; in front, it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the posterior chamber of the eye; and it is retained in its position chiefly by the suspensory ligament of the lens, already described. The capsule is much thicker in front than behind, and structureless in texture; when ruptured, the edges roll up with the outer surface innermost, like the elastic lamina of the cornea.

Fig. 450.—The crystalline lens, hardened and divided. (Enlarged.)

The anterior surface of the lens is covered by a single layer of transparent, polygonal, nucleated cells. At the circumference of the lens, these cells undergo a change in form: they become elongated, and Babucin states that he can trace the gradual transition of the cells into proper lens-fibres, with which they are directly continuous. There is no epithelium on the posterior surface.

In the *fœtus*, a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the *adult* no vessels enter its substance.

The *lens* is a transparent, biconvex body, the convexity being greater on the posterior than on the anterior surface. The central points of its anterior and posterior surfaces are known as its *anterior* and *posterior poles*. It measures from 9 to 10 mm. in the transverse diameter, and about 4 mm. in the antero-posterior. It consists of concentric layers, of which the external in the fresh state are soft and easily detached (*substantia corticalis*); those beneath are firmer, the central ones forming a hardened nucleus (*nucleus lentis*). These laminae are best demonstrated by boiling or immersion in alcohol, and consist of minute parallel fibres, which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about $\frac{1}{5000}$ of an inch. Faint lines radiate from the anterior and posterior poles to the circumference of

the lens. In the adult there may be six or more of these, but in the *fœtus* they are only three in number and diverge from each other at angles of 120° (Fig. 451). On the anterior surface one line ascends vertically and the other two diverge downward and outward. On the posterior surface one ray descends vertically

FIG. 451.—Diagram to show the direction and arrangement of the radiating lines on the front and back of the fetal lens. (A) from the front. (B) from the back.

and the other two diverge upward. They correspond with the free edges of an equal number of septa in the lens, along which the ends of the lens fibres come into apposition and are joined by transparent amorphous substance. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens terminate near the peripheral extremity of the plane on the other, and *vice versa*. The fibres of the outer layers of the lens each contain a nucleus, which together form a layer (nuclear layer) on the surface of the lens, most distinct toward its circumference.

The changes produced in the lens by age are the following :

In the *fœtus* its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.

In the adult the posterior surface is more convex than the anterior ; it is colorless, transparent, and firm in texture.

In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

The arteries of the globe of the eye are the short, long, and anterior ciliary arteries and the arteria centralis retinæ. They have been already described (see page 509).

The ciliary veins are seen on the outer surface of the choroid, and are named, from their arrangement, the *venæ vorticosæ*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Another set of veins accompany the anterior ciliary arteries and open into the ophthalmic vein.

The ciliary nerves are derived from the nasal branch of the ophthalmic and from the ciliary or ophthalmic ganglion.

Surgical Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of granular lids there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term "salmon patch" is applied. The cornea is richly supplied with

nerves, derived from the ciliary, which enter the cornea through the fore part of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic, and the cornea becomes anæsthetic. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In inflammation of the sclerotic and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In inflammation of the iris and ciliary body this zone is present, since the sclerotic speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The sclerotic may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hæmorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. Wounds of the sclerotic are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

One of the functions of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which melanotic sarcomata may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hæmorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The iris is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid this latter tunic is very apt to participate in the inflammation. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with epithelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as secondary cataract may be set up. Tumors occasionally commence in the iris; of these, cysts, which are usually congenital and sarcomatous tumors, are the most common and require removal. Gummata are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, so as to be invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hæmorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

The retina may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. Senile changes may take place in the lens, impairing its elasticity and render-

ing it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

The Appendages of the Eye.

The appendages of the eye (*tutamina oculi*) include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus—viz. the lachrymal gland, the lachrymal sac, and the nasal duct.

The **eyebrows** (*supercilia*) are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercillii, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The **eyelids** (*palpebræ*) are two thin, movable folds placed in front of the eye, protecting it from injury by their closure. The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the *Levator palpebræ superioris*. When the eyelids are opened an elliptical space (*fissura palpebrarum*) is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called *canthi*.

The *outer canthus* is more acute than the inner, and the lids here lie in close contact with the globe; but the *inner canthus* is prolonged for a short distance inward toward the nose, and the two lids are separated by a triangular space, the *lacus lachrymalis*. At the commencement of the lacus lachrymalis, on the margin of each eyelid, is a small conical elevation, the *lachrymal papilla*, the apex of which is pierced by a small orifice, the *punctum lachrymale*, the commencement of the lachrymal canal.

The **eyelashes** (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids: those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, *glands of Moll*, arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat-glands.

Structure of the Eyelids.—The eyelids are composed of the following structures, taken in their order from without inward:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate, and its ligament, Meibomian glands and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebræ.

The *integument* is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The *fibres of the Orbicularis muscle*, where they cover the palpebræ, are thin, pale in color, and possess an involuntary action.

The *tarsal plates* are two thin elongated plates of dense connective tissue

about an inch in length. They are placed one in each lid, contributing to their form and support.

The *superior*, the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebræ is attached.

The *inferior tarsal plate*, the smaller, is thinner and of an elliptical form.

The *free or ciliary margin* of these plates is thick, and presents a perfectly straight edge. The *attached or orbital margin* is connected to the circumference of the orbit by the fibrous membrane of the lids, with which it is continuous. The outer angle of each plate is attached to the malar bone by the external tarsal ligament. The inner angles of the two plates terminate at the commencement of the lacus lacrimalis; they are attached to the nasal process of the superior maxilla by the internal tarsal ligament or *tendo oculi*.

The *palpebral ligaments* are membranous expansions situated one in each lid, and are attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebræ, the inferior with the inferior tarsal plate. Externally the two ligaments fuse to form the external tarsal ligament, just referred to; internally they are much thinner and, becoming separated from the internal tarsal ligament, are fixed to the lachrymal bone immediately behind the lachrymal sac. Together, the ligaments form an incomplete septum, the *septum orbitale*, which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

FIG. 452.—Vertical section through the upper eyelid. (After Waldeyer.) *a*. Skin. *b*. Orbicularis palpebrarum. *c*. Levator palpebræ. *d*. Conjunctiva. *e*. Tarsal plate. *f*. Meibomian gland. *g*. Sebaceous gland. *h*. Eyelashes. *i*. Small hairs of skin. *j*. Sweat glands. *k*. Posterior tarsal glands.

The *Meibomian glands* (Fig. 453) are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on everting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a cæcal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement-membrane, lined at the mouths of the tubes by stratified epithelium; the deeper parts of the tubes and the secondary follicles are

lined by a layer of polyhedral cells. They are thus identical in structure with the sebaceous glands.

The *conjunctiva* is the mucous membrane of the eye. It lines the inner surface of the eyelids, and is reflected over the fore part of the sclerotic and cornea. In each of these situations its structure presents some peculiarities.

The *palpebral portion of the conjunctiva* is thick, opaque, highly vascular, and covered with numerous papillæ, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid the lachrymal ducts open on its free surface; and at the inner angle of the eye it forms a semilunar fold, the *plica semilunaris*. The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the *superior and inferior palpebral folds*, the former being the deeper of the two. Upon the *sclerotic* the conjunctiva is loosely connected to the globe: it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea* the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (see page 826). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

At the point of reflection of the conjunctiva from the lid on to the globe of the eye, termed the *fornix conjunctivæ*, are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to

FIG. 453.—The Meibomian glands, etc., seen from the inner surface of the eyelids.

lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Strohmeier, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer's patches of the small intestines, as "identical structures existing in the under eyelid of the ox."

The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the "terminal bulb."

The *caruncula lachrymalis* is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small triangular space in this situation, the *lacus lachrymalis*. It consists of a small island of skin containing sebaceous and sweat glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of mucous membrane, the concavity of which is directed toward the

cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the *membrana nictitans*.

The Lachrymal Apparatus (Fig. 454).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The lachrymal gland is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, whilst its anterior margin is closely adherent to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The fore part of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the *palpebral portion of the gland* (*accessory gland of Rosenmüller*). Its ducts, from six to twelve in number run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half

FIG. 454.—The lachrymal apparatus. Right side.

of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the Lachrymal Gland.—In structure and general appearance the lachrymal resembles the serous salivary glands (page 885). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain an oval nucleus, and the cell-protoplasm is finely fibrillated.

The lachrymal canals commence at the minute orifices, *puncta lachrymalia*, on the summit of a small conical elevation, the *lachrymal papilla*, seen on the margin of the lids at the outer extremity of the lacus lachrymalis. The *superior canal*, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the lachrymal sac. The *inferior canal* at first descends, and then, abruptly changing its course, passes almost horizontally inward to the lachrymal sac. These canals are dense and

elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium.

The **lachrymal sac** is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and nasal process of the superior maxillary. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the *tendo oculi*, and on its deep surface it is crossed by the Tensor tarsi muscle (Horner's muscle, page 302), which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the lachrymal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.

The **nasal duct** is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the *valve of Hasner*, formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. This membrane in the lachrymal sac and nasal duct is covered with columnar epithelium, as in the nose. This epithelium is in places ciliated.

Surface Form.—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.

When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lachrymalia*, the commencement of the lachrymal canals. They are best seen by everting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle (page 119), which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the *tendo oculi* or internal tarsal ligament. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Surgical Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices, and thus produce an eversion of the lid known as *ectropion*. Inversion

of the lids (*entropion*) from spasm of the *Orbicularis palpebrarum* or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as *nævi*. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary "sty." The Meibomian glands are affected in the so-called "tarsal tumor;" the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis ciliaris*, or "blear-eye." Irregular or disorderly growth of the eyelashes not unfrequently occurs, some of them being turned toward the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The *Orbicularis palpebrarum* may be the seat of spasm, either in the form of slight quivering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerve. The *Orbicularis* may be paralyzed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. In paralysis of the *Levator palpebræ superioris* there is drooping of the upper eyelid and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. In these latter injuries adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of emphysema after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure.

The lachrymal gland is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumors, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canaliculi may also become occluded as the result of burns or injury; overflow of the tears may in addition result from deviation of the puncta or from chronic inflammation of the lachrymal sac. This latter condition is set up by some obstruction to the nasal duct frequently occurring in tubercular subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula.

THE EAR.

The organ of hearing is divisible into three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

The External Ear.

The external ear consists of an expanded portion named *pinna* or *auricle*, and the auditory canal or *meatus*. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The *pinna*, or *auricle* (Fig. 455), is of an ovoid form, with its larger end directed

upward. Its outer surface is irregularly concave, directed slightly forward, and presents numerous eminences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these, names have been assigned. Thus the external prominent rim of the auricle is called the *helix*. Another curved prominence, parallel with and in front of the helix, is called the *antihelix*; this bifurcates above, so as to enclose a triangular depression, the *fossa of the antihelix* (*fossa triangularis*). The narrow curved depression between the helix and antihelix is called the *fossa of the helix* (*Scapha*); the antihelix describes a curve round a deep, capacious cavity, the *concha*, which is partially divided into two parts by the *crus helicis* or the commencement of the helix; the upper part is termed the *cymba conchæ*, the lower part the *cavum conchæ*. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the *tragus*, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisura intertragica*) is a small tubercle, the *antitragus*. Below this is the *lobule*, composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna. Where the helix turns downward a small tubercle, the *tubercle of Darwin*, is frequently seen. This tubercle is very evident about the sixth month of foetal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys.

The cranial surface of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, *e. g.*, *eminentia conchæ*, *eminentia triangularis*, etc.

Structure of the Pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage, covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles; and to the commencement of the external auditory canal by fibrous tissue.

The *integument* is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

The *cartilage of the pinna* consists of one single piece: it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the auricle: thus it does not form a constituent part of the lobule; it is deficient also between the tragus and beginning of the helix, the notch between them being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the *spina helicis*, while the lower part of the helix is prolonged downward as a tail-like process, the *cauda helicis*; this is separated from the antihelix by a fissure, the *fissura antitragohelicina*. The cartilage of the pinna presents several intervals or fissures in its substance which partially separate the different parts. The fissure of the helix is a short vertical slit, situated at the fore part of the pinna. Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. The cartilage of the pinna is very pliable, elastic, of a yellowish color, and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

The *ligaments of the pinna* consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The *extrinsic ligaments*, the most important, are two in number, anterior and posterior. The *anterior ligament* extends from the spina helicis and tragus to the root of the zygoma. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The chief *intrinsic ligaments* are: (1) a strong fibrous band, stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (2) a band which extends

between the anti-helix and the cauda helices. Other less important bands are found on the cranial surface of the pinna.

The *muscles of the pinna* (Fig. 456) consist of two sets: 1. The *extrinsic*, which connect it with the side of the head, moving the pinna as a whole—viz., the *Attollens*, *Attrahens*, and *Retrahens auriculum* (page 301); and 2. The *intrinsic*, which extend from one part of the auricle to another, viz.:

Helicis major.
Helicis minor.
Tragicus.

Antitragicus.
Transversus auriculæ.
Obliquus auriculæ.

The *Musculus helicis major* is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises, below, from the cauda helices, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

FIG. 455.—The pinna, or auricle. Outer surfaces.

FIG. 456.—The muscles of the pinna.

The *Musculus helicis minor* is an oblique fasciculus which covers the crus helices.

The *Tragicus* is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The *Antitragicus* arises from the outer part of the antitragus: its fibres are inserted into the cauda helices and antihelix. This muscle is usually very distinct.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The *Obliquus auriculæ* (Tod) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are the posterior auricular from the external carotid, the anterior auricular from the temporal, and an auricular branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *nerves* are: the auricularis magnus, from the cervical plexus; the auricu-

lar branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus, and the occipitalis major or internal branch of the posterior division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The **Auditory Canal** (*meatus auditorius externus*) extends from the bottom of the concha to the membrana tympani (Fig. 457). It is about an inch and a half in length if measured from the tragus; from the bottom of the concha its length is about an inch. It forms a sort of S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the *isthmus*, in the osseous portion, about three-quarters of an inch from the bottom of the concha. The membrana tympani, which occupies the termination of the meatus, is obliquely directed, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

FIG. 457.—Transverse section of external auditory meatus and tympanum. Left side. (Gegenbaur.)

The *cartilaginous portion* is about one-third of an inch (8 mm.) in length, it is formed by the cartilage of the pinna, prolonged inward, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures (*incisurae Santorini*), which extend through the cartilage in a vertical direction.

The *osseous portion* is about two-thirds of an inch (16 mm.) in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about two lines; it is marked, except at its upper part, by a narrow groove, the *sulcus tympanicus*, for the insertion of the membrana tympani. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate of bone, which, in the foetus, exists as a separate ring (*annulus tympanicus*), incomplete at its upper part. See section on Osteology.

The *skin* lining the meatus is very thin, adheres closely to the cartilaginous and osseous portion of the tube, and covers the surface of the membrana tympani, forming its outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

Relations of the Meatus.—In front of the osseous part is the condyle of the mandible, which, however, is separated from the cartilaginous part by the retro-mandibular part of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air-cells, separated from it by a thin layer of bone.

The *arteries* supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The *nerves* are chiefly derived from the auriculo-temporal branch of the inferior maxillary nerve and the auricular branch of the pneumogastric.

Surface Form.—At the point of junction of the osseous and cartilaginous portions the tube forms an obtuse angle, which projects into the tube at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ears. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, or flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is very short, the osseous part being very deficient, and consisting merely of a bony ring (*annulus tympanicus*), which supports the membrana tympani. In the foetus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle, (about 55°) while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

The Middle Ear, or Tympanum.

The middle ear, or *tympanum*, is an irregular cavity, compressed from without inward, and situated within the petrous bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the meatus auditorius externally, and the labyrinth internally. It is filled with air, and communicates with the naso-pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear.

The tympanic cavity consists of two parts: the *atrium* or *tympanic cavity* proper, opposite the tympanic membrane, and the *attic* or *epitympanic* recess, above the level of the upper part of the membrane; the latter contains the upper half of the

malleus and the greater part of the incus. Its diameter, including the attic, measures about 15 mm. vertically and transversely. From without inward it measures about 6 mm. above and 4 mm. below; opposite the centre of the tympanic membrane it is only about 2 mm. It is bounded externally by the membrana tympani and meatus; internally, by the outer surface of the internal ear; and communicates, behind, with the mastoid antrum and through it with the mastoid cells; and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminæ, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The **roof** (*paries tegmentalis*) is broad, flattened, and formed of a thin plate of bone (*tegmen tympani*), which separates the cranial and tympanic cavities. It is prolonged backward so as to roof in the mastoid antrum; it is also carried forward to cover in the canal for the Tensor tympani muscle,

The **floor** (*paries jugularis*) is narrow, and is separated by a thin plate of bone (*fundus tympani*) from the jugular fossa. It presents, near the inner wall, a small aperture for the passage of Jacobson's nerve.

The **outer wall** is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. This ring of bone is incomplete at its upper part, forming a notch (*incisura Rivini*). Close to it are three small apertures; the iter chordæ posterius, the Glaserian fissure, and the iter chordæ anterior.

FIG. 458.—View of inner wall of tympanum. (Enlarged.)

The *iter chordæ posterius* is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends in front of the aquæductus Fallopii, and terminates in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The *Glaserian fissure* opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The *iter chordæ anterior* is seen at the inner end of the preceding fissure; it leads into a canal (*canal of Huguier*), which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The **internal wall of the tympanum** (*paries labyrinthica*) (Fig. 458) is vertical in direction, and looks directly outward. It presents for examination the following parts:

Fenestra ovalis.
Fenestra rotunda.

Promontory.
Ridge of the aquæductus Fallopii.

The *fenestra ovalis* is a reniform opening leading from the tympanum into the vestibule; its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes, which is connected to the margin of the foramen by an annular ligament.

The *fenestra rotunda* is an aperture placed at the bottom of a funnel-shaped depression leading into the cochlea. It is situated below and rather behind the *fenestra ovalis*, from which it is separated by a rounded elevation, the *promontory*; it is closed in the recent state by a membrane (*membrana tympani secundaria*, Scarpa). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external, or mucous, derived from the mucous lining of the tympanum; the internal, from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The *promontory* is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestræ, and is furrowed on its surface by three small grooves, which lodge branches of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramid.

The *rounded eminence of the aquæductus Fallopii*, the prominence of the bony canal in which the facial nerve is contained, traverses the inner wall of the tympanum above the *fenestra ovalis*, and behind that opening curves nearly vertically downward along the posterior wall.

The **posterior wall of the tympanum** (*paries mastoidea*) is wider above than below, and presents for examination the

Opening of the antrum.

Pyramid.

The *opening of the antrum* is a large irregular aperture, which extends backward from the epitympanic recess and leads into a considerable air space, the *antrum mastoideum* (see page 68). The antrum communicates with large irregular cavities contained in the interior of the mastoid process, the *mastoid air-cells*. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The *pyramid* is a conical eminence situated immediately behind the *fenestra ovalis*, and in front of the vertical portion of the eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the *fenestra ovalis*, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aquæductus Fallopii and transmits the nerve which supplies the Stapedius.

The **anterior wall of the tympanum** (*paries carotica*) is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone, perforated by the tympanic branch of the internal carotid artery. It presents for examination the

Canal for the Tensor tympani.

Orifice of the Eustachian tube.

The *processus cochleariformis*.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being separated from each other by a thin, delicate, horizontal plate of bone, the *processus cochleariformis*. These canals run from the tympanum forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The *canal for the Tensor tympani* is the superior and the smaller of the two; it is rounded and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the *fenestra ovalis*. The *processus cochleariformis* passes backward below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the *fenestra ovalis* and terminates by curving outward so as to form a pulley over which the tendon passes.

The *Eustachian tube* is the channel through which the tympanum communicates with the pharynx. Its length is an inch and a half (36 mm.), and its direction downward, forward, and inward, forming an angle of about 45° with the sagittal plane and one of from 30° to 40° with the horizontal plane. It is formed partly of bone, partly of cartilage and fibrous tissue.

The *osseous portion* is about half an inch in length. It commences in the anterior wall of the tympanum, below the *processus cochleariformis*, and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The *cartilaginous portion*, about an inch in length, is formed of a triangular plate of elastic fibro-cartilage, the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the naso-pharynx, where it forms an elevation or cushion behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outward so as to present on transverse section the appearance of a hook; a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. The cartilage is fixed to the base of the skull, and lies in a groove between the petrous-temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate. The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downward a little more than the latter. The diameter of the canal is not uniform throughout, being greatest at the pharyngeal orifice and least at the junction of the bony and cartilaginous portions, where it is named the *isthmus*; it again expands somewhat as it approaches the tympanic cavity. The position and relations of the pharyngeal orifice are described with the anatomy of the naso-pharynx. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the *tube-tonsil*. The tube is opened during deglutition by the *Salpingopharyngeus* and *Dilator tubæ* muscles.

The *membrana tympani* separates the cavity of the tympanum from the bottom of the external meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward so as to form an angle of about 55° with the floor of the meatus. The greater part of its circumference is thickened to form an annular ring which is fixed in a groove, the *sulcus tympanicus*, at the inner extremity of the meatus. This sulcus is deficient superiorly at the incisure or notch of Rivinus. From the extremities of this notch two bands, the *anterior* and *posterior malleolar folds*, are prolonged to the short process of the malleus. The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the *membrana flaccida* of Shrapnell; in it a small orifice is sometimes seen. The handle of the malleus is firmly attached to the inner aspect of the membrane as far as its centre, which it draws inward toward the cavity of the tympanum. The outer surface of the membrane is thus concave, and the most depressed part of this concavity is named the *umbo* or *navel*.

Structure.—This membrane is composed of three layers, an external (cuticular), a middle (fibrous), and an internal (mucous). The *cuticular lining* is derived from the integument lining the meatus. The fibrous layer consists of two strata, an external, of *radial fibres*, which diverge from the handle of the malleus, and an internal, of *circular fibres*, which are plentiful around the circumference but sparse and scattered near the centre of the membrane. Branched or *dendritic* fibres, as pointed out by Grüber, are also present, especially in the posterior half of the membrane.

The arteries are derived from the deep auricular branch of the internal maxil-

lary, which ramifies beneath the cuticular layer and from the stylo-mastoid branch of the posterior auricular and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The superficial veins open into the external jugular; those on the mucous surface drain themselves partly into the lateral sinus and veins of the dura mater and partly into a plexus on the Eustachian tube. The membrane receives its nervous supply from the auriculo-temporal branch of the inferior maxillary, the auricular branch of the vagus, and the tympanic branch of the glosso-pharyngeal.

Ossicles of the Tympanum (Fig. 459).

The tympanum is traversed by a chain of movable bones, three in number, the *malleus*, *incus*, and *stapes*. The first is attached to the *membrana tympani*, the last to the *fenestra ovalis*, the *incus* being placed between the two, and is connected to both by delicate articulations.

The **Malleus**, so named from its fancied resemblance to a hammer, consists of a head, neck, and three processes—the handle or *manubrium*, the *processus gracilis*, and the *processus brevis*.

The *head* is the large upper extremity of the bone; it is oval in shape, and articulates posteriorly with the *incus*, being free in the rest of its extent. The facet for articulation with the *incus* is constricted near the middle, and is divided by a ridge into an upper, larger, and lower, lesser part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the *cog-tooth* or *spur* of the malleus.

The *neck* is the narrow contracted part just beneath the head; and below this is a prominence, to which the various processes are attached.

The *manubrium* is a vertical process of bone, which is connected by its outer margin with the *membrana tympani*. It is directed downward, inward, and backward; it decreases in size toward its extremity, where it is curved slightly forward, and flattened from within outward. On the inner side, near its upper end, is a slight projection, into which the tendon of the *Tensor tympani* is inserted.

The *processus gracilis* is a long and very delicate process, which passes from the eminence below the neck forward and outward to the Glaserian fissure, to which it is connected by ligamentous fibres. In the fœtus this is the longest process of the malleus, and is in direct continuity with the cartilage of Meckel.

The *processus brevis* is a slight conical projection, which springs from the root of the *manubrium*; it is directed outward, and is attached to the upper part of the tympanic membrane.

The **Incus** has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth, with two roots, which differ in length, and are widely separated from each other. It consists of a body and two processes.

FIG. 459.—The small bones of the ear, seen from the outside. (Enlarged.)

The *body* is somewhat quadrilateral but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus; in the fresh state it is covered with cartilage and the joint lined with synovial membrane.

The two processes diverge from one another nearly at right angles.

The *short process*, somewhat conical in shape, projects nearly horizontally backward, and articulates with a depression, the *fossa incudis*, in the lower and back part of the epitympanic recess.

The *long process*, longer and more slender than the preceding, descends nearly

vertically behind and parallel to the handle of the malleus, and, bending inward, terminates in a rounded globular projection, the *os orbiculare* or *lenticular process*, which is tipped with cartilage, and articulates with the head of the stapes. In the fœtus the *os orbiculare* exists as a separate bone.

The **Stapes**, so called from its close resemblance to a stirrup, consists of a head, neck, two crura, and a base.

The *head* presents a depression, tipped with cartilage, which articulates with the *os orbiculare*.

The *neck*, the constricted part of the bone succeeding the head, receives the insertion of the *Stapedius* muscle.

The *two crura* diverge from the neck and are connected at their extremities by a flattened, oval-shaped plate (the *base*), which forms the foot-plate of the stirrup and is fixed to the margin of the fenestra ovalis by ligamentous fibres. Of the two crura, the anterior is shorter and less curved than the posterior.

Ligaments of the Ossicula.—These small bones are connected with each other and with the walls of the tympanum by ligaments, and moved by small muscles. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane. The ligaments connecting the ossicula with the walls of the tympanum are five in number—three for the malleus, one for the incus, and one for the stapes.

The *anterior ligament of the malleus* was formerly described by Sömmerring as a muscle (*Lazator tympani*). It is now, however, believed by most observers to consist of ligamentous fibres only. It is attached by one extremity to the neck of the malleus, just above the processus gracilis, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure to reach the spine of the sphenoid.

The *superior ligament of the malleus* is a delicate, round bundle of fibres which descends perpendicularly from the roof of the epitympanic recess to the head of the malleus.

The *external ligament of the malleus* is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring (*incisura Rivini*) to the short process of the malleus.

The *posterior ligament of the incus* is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior and lower part of the epitympanic recess, near the margin of the opening of the mastoid cells.

The inner surface and the circumference of the base of the stapes are covered with hyaline cartilage, and the *annular ligament of the stapes* connects the circumference of the base to the margin of the fenestra ovalis.

A *superior ligament of the incus* has been described by Arnold, but it is little more than a fold of mucous membrane.

The **muscles of the tympanum** are two :

Tensor tympani.

Stapedius.

The *Tensor tympani*, the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward round the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. It is supplied by a branch from the otic ganglion.

The *Stapedius* arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony

spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The Tensor tympani draws the membrana tympani inward and thus heightens its tension. The Stapedius draws the head of the stapes backward, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre: in doing this the back part of the base would be pressed inward toward the vestibule, while the fore part would be drawn from it. It probably compresses the contents of the vestibule.

The **mucous membrane of the tympanum** is continuous with the mucous membrane of the pharynx through the Eustachian tube. It invests the ossicula, and the muscles and nerves contained in the tympanic cavity; forms the internal layer of the membrana tympani, and the outer layer of the membrana tympani secundaria, and is reflected into the mastoid antrum and cells, which it lines throughout. It forms several vascular folds, which extend from the walls of the tympanum to the ossicles; of these, one descends from the roof of the tympanum to the head of the malleus and upper margin of the body of the incus, a second invests the Stapedius muscle: other folds invest the chorda tympani nerve and the Tensor tympani muscle. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honey-comb appearance. One of these pouches is well marked—viz., the *pouch of Prussak*, which lies between the neck of the malleus and the membrana flaccida. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that covering the pyramid, ossicula, and membrana tympani possesses a flattened non-ciliated epithelium. In the antrum and mastoid cells its epithelium is also non-ciliated. In the osseous portion of the Eustachian tube the membrane is thin; but in the cartilaginous portion it is very thick, highly vascular, covered with ciliated epithelium, and provided with numerous mucous glands.

The arteries supplying the tympanum are six in number. Two of them are larger than the rest—viz., the tympanic branch of the internal maxillary, which supplies the membrana tympani; and the stylo-mastoid branch of the posterior auricular, which supplies the back part of the tympanum and mastoid cells. The smaller branches are—the petrosal branch of the middle meningeal, which enters through the hiatus Fallopii; a branch from the ascending pharyngeal and another from the Vidian, which accompany the Eustachian tube; and the tympanic branch from the internal carotid, given off in the carotid canal and perforating the thin anterior wall of the tympanum.

The veins of the tympanum terminate in the pterygoid plexus and in the superior petrosal sinus.

The nerves of the tympanum constitute the tympanic plexus, which ramifies upon the surface of the promontory. The plexus is formed by (1) the tympanic branch of the glosso-pharyngeal; (2) the small deep petrosal nerve; (3) the small superficial petrosal nerve; and (4) a branch which joins the great superficial petrosal.

The *tympanic branch of the glosso-pharyngeal* (Jacobson's nerve) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The *small deep petrosal nerve* from the carotid plexus of the sympathetic passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. The *small superficial petrosal nerve*, derived from the otic ganglion, passes through a foramen in the middle fossa of the base of the skull (sometimes the foramen ovale), passes backward and enters the petrous bone through a small aperture, situated external to the hiatus Fallopii on the anterior surface of this bone; it then courses downward through the bone, and, passing by the gangliform enlargement of the facial nerve, receives a connecting filament from it and enters the tympanic cavity, where

it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The *branches of distribution* of the tympanic plexus are distributed to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as a branch from the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the fifth through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The *chorda tympani* nerve crosses the tympanic cavity. It is given off from the facial as it passes vertically downward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, *iter chordæ posterius*, already described (page 853), and becomes invested with mucous membrane. It passes forward, through the cavity of the tympanum, crossing internal to the *membrana tympani* and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through the *iter chordæ anterioris*, or *canal of Huguier*. It is invested by the fold of mucous membrane already mentioned, and therefore lies between the mucous and fibrous layers of the *membrana tympani*.

The Internal Ear or Labyrinth.

The **internal ear** is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the **labyrinth**, from the complexity of its shape, and consists of two parts: the *osseous labyrinth*, a series of cavities channelled out of the substance of the petrous bone, and the *membranous labyrinth*, the latter being contained within the former.

The Osseous Labyrinth.

The osseous labyrinth consists of three parts: the *vestibule*, *semicircular canals*, and *cochlea*. These are cavities hollowed out of the substance of the bone, and

FIG. 460.—The osseous labyrinth laid open. (Enlarged.)

lined by periosteum; they contain a clear fluid, perilymph, or liquor Cotunnii, in which the membranous labyrinth is situated.

The **Vestibule** (Fig. 460) is the common central cavity of communication

between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before backward, as well as from above downward, and about one-eighth of an inch from without inward. On its *outer* or *tympanic wall* is the fenestra ovalis, closed, in the recent state, by the base of the stapes, and its annular ligament. On its *inner wall*, at the fore part, is a small circular depression, *fovea hemisphærica* or *recessus sphæricus*, which is perforated, at its anterior and inferior part, by several minute holes (*macula cribrosa media*) for the passage of filaments of the auditory nerve to the sacculus; and behind this depression is a vertical ridge, the *crista vestibuli*. This ridge bifurcates below to enclose a small depression, the *fossa cochlearis*, which is perforated by a number of holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. At the hinder part of the inner wall is the orifice of the *aquæductus vestibuli*, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and contains a tubular prolongation of the lining membrane of the vestibule, the *ductus endolymphaticus*, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. On the *upper wall* or *roof* is a transversely oval depression, *fovea semi-elliptica*, separated from the fovea hemisphærica by the crista vestibuli already mentioned. *Behind*, the semicircular canals open into the vestibule by five orifices. In *front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea by an orifice, *apertura scalæ vestibuli cochleæ*.

The **Semicircular canals** are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and describe the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the *ampulla*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The *superior semicircular canal* is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, communicates by a distinct orifice in the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal to form the *crus commune*, which opens into the upper and inner part of the vestibule.

The *posterior semicircular canal*, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three; its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned.

The *external* or *horizontal canal* is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The **Cochlea** bears some resemblance to a common snail-shell: it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward, with a slight inclination downward, toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear division of the auditory nerve. It measures nearly a quarter of an inch (5 mm.) from base to apex, and its breadth across the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the *modiolus* or *columella*; of a canal, the inner wall of which is formed by the central axis, wound spirally around it for two turns and three-quarters, from the base to the

apex, and of a delicate lamina (the *lamina spiralis ossea*) which projects from the modiolus, and, following the windings of the canal, partially subdivides into two. In the recent state certain membranous layers are attached to the free border of this lamina, which project into the canal and completely separate it into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the *helicotrema*.

The *modiolus* or *columella* is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its base is broad, and appears at the bottom of the internal auditory meatus, where it corresponds with the area cochleæ; it is perforated by numerous orifices, which transmit filaments of the cochlear division of the auditory nerve, the nerves for the first turn and a half being transmitted through the foramina of the tractus spiralis foraminosus; the fibres for the apical turn passing up through the foramen centrale. The foramina of the tractus spiralis foraminosus pass up through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form a spiral canal (*canalis spiralis modioli*), which follows the course of the attached margin of the lamina spiralis ossea and lodges the ganglion spirale. The foramen centrale is continued as a canal up the middle of the modiolus to its apex. The axis diminishes rapidly in size in the second and succeeding coil.

The bony canal of the cochlea (Fig. 461) takes two turns and three-quarters round the modiolus. It is a little over an inch in length (about 30 mm.), and

FIG. 461.—The cochlea laid open. (Enlarged.)

diminishes gradually in size from the base to the summit, where it terminates in a *cul-de-sac*, the *cupola*, which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus toward the tympanum and vestibule, and presents three openings. One, the *fenestra rotunda*, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the *membrana tympani secundaria*. Another aperture, of an elliptical form, enters the vestibule. The third is the aperture of the aquæductus cochleæ, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone and transmits a small vein, and also forms a communication between the subarachnoidean space of the skull and the perilymph contained in the scala tympani.

The *lamina spiralis ossea* is a bony shelf or ledge which projects outward from the modiolus into the interior of the spiral canal, and, like the canal, takes two and three-quarter turns round the modiolus. It reaches about half-way toward the outer wall of the spiral tube, and partially divides its cavity into two passages or scalæ, of which the upper is named the *scala vestibuli*, while the lower is termed the *scala tympani*. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the *hamulus*, which assists to form the boundary of a small opening, the *helicotrema*, by which the two scalæ communicate with each other. From the *canalis spiralis modioli* numerous foramina pass outward through the osseous spiral lamina as far as its outer or free edge. In the lower part of the first

turn a second bony lamina (*lamina spiralis secundaria*) projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the *fissura vestibuli*, is seen between them.

The Membranous Labyrinth (Fig. 462).

The **membranous labyrinth** is contained within the bony cavities just described, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the *perilymph*. It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the *endolymph*, and on it the ramifications of the auditory nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the *utricle* and the *sacculle*. The *utricle* is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica and the part below it. That portion which is lodged in the fovea forms a sort of pouch or *cul-de-sac*, the floor and anterior wall of which are much thicker than elsewhere, and form the *macula acustica utricularis*, which receives the utricular filaments of the auditory nerve and has attached to its

FIG. 462.—The membranous labyrinth. (Enlarged.)

internal surface a layer of calcareous particles (otoliths). The cavity of the utricle communicates behind with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal, which joins with a canal from the sacculle to form the *ductus endolymphaticus*.

The *sacculle* is the smaller of the two vestibular sacs; it is globular in form, lies in the fovea hemisphærica near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the *macula saccularis*, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall is given off a canal, which joins with a similar canal given off from the utricle to form the *ductus endolymphaticus*. This duct passes along the aqueductus vestibuli and ends in a blind pouch on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. From the lower part of the sacculle a short tube, the *canalis reuniens* of Hensen, passes downward and outward to open into the ductus cochlearis (Fig. 462).

The *membranous semicircular canals* are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar,

and present at one end an ampullary enlargement. They open by five orifices into the utricle, one opening being common to two canals. In the ampullæ the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the *septum transversum*, in which the nerves end.

The utricle, saccule, and membranous canals are held in position by numerous fibrous bands which stretch across the space between them and the bony walls.

Structure.—The walls of the utricle, saccule, and semicircular canals consist of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and pigment-cells analogous to those in the pigment coat of the retina. The *middle layer*, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells. In the maculæ of the utricle and saccule, and in the transverse septa of the ampullæ of the canals, the middle coat is thickened and the epithelium is columnar, and consists of *supporting cells* and *hair-cells*, the free ends of the latter being surmounted by a long, tapering filament (auditory hair) which projects into the cavity. The filaments of the auditory nerve enter these parts, and, having pierced the outer and thickened middle layer, they lose their medullary sheath, and their axis-cylinders ramify between the hair-cells.

Two small rounded bodies termed *otoliths*, and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous

FIG. 463.—Floor of scala media, showing the organ of Corti, etc.

tissue, are contained in the walls of the utricle and saccule opposite the distribution of the nerves. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullæ of the semicircular canals.

The **membranous cochlea**, *ductus cochlearis*, or **scala media** consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall. The manner in which it is formed will now be described.

The osseous spiral lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. A membrane, the *membrana basilaris*, stretches from its free edge to the outer wall of the cochlea, and completes the roof of the scala tympani. A second and more delicate membrane, the *membrane of Reissner*, extends from the thickened periosteum covering the lamina spiralis ossea to the outer wall of the cochlea, to which it is attached at some little distance above the *membrana basilaris*. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the *membranous canal of the cochlea*, *ductus cochlearis*, or **scala media**. It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and its floor by the

membrana basilaris, and the outer part of the lamina spiralis ossea, on the former of which is placed the organ of Corti. Reissner's membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, which forms the outer wall of the ductus cochlearis, is greatly thickened and altered in character, forming what is called the *ligamentum spirale*. It projects inward below as a triangular prominence, the *crista basilaris*, which gives attachment to the outer edge of the membrana basilaris, and immediately above which is a concavity, the *sulcus spiralis externus*. The upper portion of the ligamentum spirale contains numerous capillary loops and small blood-vessels, and forms what is termed the *stria vascularis*.

The lamina spiralis ossea consists of two plates of bone extending outward; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the *limbus laminae spiralis*, and this terminates externally in a concavity, the *sulcus spiralis internus*, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the *labium vestibulare*; the lower part, prolonged and tapering, is called the *labium tympanicum*, and is perforated by numerous foramina (*foramina nervosa*) for the passage of the cochlear nerves. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free margin of the labium, and have been named by Huschke the *auditory teeth*. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the *zona arcuata*: it supports the organ of Corti. The outer is thicker and striated, and is termed the *zona pectinata*. The under surface of the membrane is covered by a layer of vascular connective tissue. One of these vessels is somewhat larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel.

Organ of Corti.¹—This organ (Fig. 464) is situated upon the inner part of the membrana basilaris, and appears at first sight as a papilla, winding spirally

FIG. 464.—Section through the organ of Corti. Magnified. (G. Retzius.)

throughout the whole length of the ductus cochlearis, from which circumstance it has been designated the *papilla spiralis*. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a pianoforte. Of these cells, the two central ones are rodlike bodies

¹ Corti's original paper is in the *Zeitschrift f. Wissen. Zool.*, iii., 109.

and are called the inner and outer rods of Corti. They are placed on the basilar membrane, at some little distance from each other, but are inclined toward each other, so as to meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the *tunnel of Corti*, between them and the basilar membrane, which ascends spirally through the whole length of the cochlea.

The *inner rods*, some 6000 in number, are more numerous than the outer ones, and rest on the basilar membrane, close to the labium tympanicum; they project obliquely upward and outward, and terminate above in expanded extremities which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells (*inner hair-cells*), surmounted by a brush of fine, stiff, hairlike processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

The *outer rods*, numbering about 4000, also rest by a broad foot on the basilar membrane; they incline upward and inward, and their upper extremity resembles the head and bill of a swan: the back of the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outward as a phalangeal process of the membrana reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or

FIG. 465.—Longitudinal section of the cochlea, showing the relations of the scalæ, the ganglion spirale, etc. S. V. Scala vestibuli. S. T. Scala tympani. S. M. Scala media. L. S. Ligamentum spirale. G. S. Ganglion spirale.

four successive rows of epithelial cells, more elongated than those found on the internal side of the inner rod. but, like them, furnished with minute hairs or cilia. These are termed the *outer hair-cells*, in contradistinction to the *inner hair-cells* above referred to. There are about 12,000 outer hair-cells, and about 3500 inner hair-cells.

The hair-cells are somewhat oval in shape; their free extremities are on a level with the heads of Corti's rods, and from each some twenty fine hairlets

project and are arranged in the form of a crescent, the concavity of which opens inward. The deep ends of the cells are rounded and contain large nuclei: they reach only as far as the middle of Corti's rods, and are in contact with the ramifications of the nervous filaments. Between the rows of the outer hair-cells are rows of supporting cells, called the *cells of Deiters*; their expanded bases are planted on the basilar membrane, while their opposite ends present a clubbed extremity or *phalangeal* process. Immediately to the outer side of Deiters's cells are some five or six rows of columnar cells, the *supporting cells of Hensen*. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the *cells of Claudius*. A space is seen between the outer rods of Corti and the adjacent hair-cells; this is called the *space of Nuel*.

The *lamina reticularis* or *membrane of Kölliker* is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of "minute fiddle-shaped cuticular structures," called *phalanges*, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters's cells.

Covering over these structures, but not touching them, is the *membrana tectoria*, or membrane of Corti, which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair-cells, is a clear band, named *Hensen's stripe*. Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters's cells (Retzius).

The *inner surface of the osseous labyrinth* is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater. This membrane is continued across the fenestra ovalis and rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the *aqua labyrinthi*, *liquor Cotunnii*, or *perilymph* (Blainville).

The scala media is closed above and below. The upper blind extremity is termed the *lagena*, and is attached to the cupola at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives the *canalis reuniens of Hensen* (Fig. 462), a very delicate canal, by which the ductus cochlearis is brought into continuity with the sacculæ.

The *arteries of the labyrinth* are the internal auditory, from the basilar, and the stylo-mastoid, from the posterior auricular. The internal auditory divides at the bottom of the internal meatus into two branches: cochlear and vestibular.

The cochlear branch subdivides into from twelve to fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the substance of the lamina spiralis.

The vestibular branches accompany the nerves, and are distributed, in the form of a minute capillary network, in the substance of the membranous labyrinth.

The *veins* (auditory) of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, terminate in the posterior part of the superior petrosal sinus or in the lateral sinus.

The *auditory nerve*, the special nerve of the sense of hearing, divides, at the

bottom of the internal auditory meatus, into two branches, the cochlear and vestibular.

The *vestibular nerve*, the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the *ganglion of Scarpa*; it divides into three branches which pass through minute openings at the upper and back part of the bottom of the meatus (*area vestibular superior*), and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The nervous filaments enter the ampullary enlargements opposite the septum transversum, and arborize around the hair-cells. In the utricle and saccule the nerve-fibres pierce the *membrana propria* of the maculæ, and end in arborizations round the hair-cells.

The *cochlear nerve* gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the *area vestibularis inferior*, which lies at the lower and back part of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the *foramen singulare*.

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the *tractus foraminosus*, those for the apical coil through the *canalis centralis*, and the nerves bend outward to pass between the lamellæ of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the *ganglion spirale*, consisting of bipolar nerve-cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centrally to the brain and the other peripherally to the hair-cells of Corti's organ. Reaching the outer edge of the osseous spiral lamina, they pass through the foramina in the *labium tympanicum*, and end, some by arborizing around the bases of the inner hair-cells, while others pass between Corti's rods and through the tunnel, to terminate in a similar manner in relation to the outer hair-cells.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hæmatoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for earrings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and *membrana tympani* can be brought into view. The points to be noted are, the presence of wax or foreign bodies, the size of the canal, and the condition of the *membrana tympani*. The accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the *membrana tympani* and possibly the contents of the tympanum. The calibre of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by peristitis; by polypi, sebaceous tumors, and exostoses. The *membrana tympani*, when seen in a healthy ear, "reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion." From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while near the upper part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow, a loud report, a wound, or as the result of suppuration in the middle ear.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone;

the anterior wall is separated from the temporo-mandibular joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells; hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-mandibular joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the auricular branch of the pneumogastric, the auriculo-temporal, and the auricularis magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the pneumogastric, or of yawning from implication of the auriculo-temporal. No doubt also the association of earache with toothache in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal maxillary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporal lobe of the brain. Its floor is immediately above the jugular fossa behind and the carotid canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum from extension of the inflammation through the bony roof: thrombosis of the lateral sinus, with or without pyæmia, by extension through the floor; or mastoid abscess by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Dilator tubea muscle. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an india-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth; both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard, if the membrane is sound, by means of a piece of india-rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, close to the septum, with the point touching the floor, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an india-rubber tube.

THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food consists of the alimentary canal and of certain accessory organs.

The alimentary canal is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement, the mouth, we find provision made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the pharynx and the œsophagus, which convey the food into that part of the alimentary canal (the stomach) in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines the nutritive principles of the food (the *chyle*) are separated, by its admixture with the bile, pancreatic and intestinal fluids, from that portion which passes into the large intestine, most of which is expelled from the system.

THE MOUTH.

The **mouth** (*oral* or *buccal cavity*) is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication of the food takes place (Fig. 466). It consists of two parts; an outer, smaller portion, the vestibule (*vestibulum oris*), and an inner, larger part, the cavity proper of the mouth (*cavum oris proprium*).

The *vestibulum oris* is a slit-like aperture, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. Above and below it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid glands, and communicates, when the jaws are closed, with the *cavum oris* by an aperture on each side behind the wisdom teeth.

The *cavum oris proprium* is bounded laterally and in front by the alveolar arches with their contained teeth; behind it communicates with the pharynx by a constricted aperture termed the *isthmus faucium*. It is roofed in by the hard and soft palate, while the greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual glands.

The *mucous membrane* lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The **lips** are two fleshy folds which surround the orifice of the mouth, formed

externally by integument and internally by mucous membrane, between which are found the Orbicularis oris muscle, the coronary vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the *frænum labii superioris* and *inferioris*—the former being the larger of the two.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris round the orifice of the mouth. They are rounded in form, about the size of small peas, their ducts opening by small orifices upon the mucous membrane. In structure they resemble the salivary glands.

The *cheeks* form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining mem-

FIG. 466.—Sectional view of the nose, mouth, pharynx, etc.

gums, and it is continuous behind with the lining membrane of the soft palate. Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland. The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz., the Zygomatici, Risorius Santorini, and Platysma myoides.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle: they are similar in structure to the labial glands, but smaller. Two or three of larger size than the rest are placed between the Masseter and Buccinator muscles; their ducts open into the mouth opposite the last molar tooth. They are called *molar glands*.

The *gums* are composed of a dense fibrous tissue closely connected to the

periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillæ; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

THE TEETH.

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the *temporary, deciduous, or milk teeth*. The second set are named *permanent*.

FIG. 467.—Deciduous teeth. Left side.

The *temporary teeth* are twenty in number—four incisors, two canine, and four molars, in each jaw (Fig. 467).

The *permanent teeth* are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspids, and six molars in each jaw (Fig. 468).

General Characters.—Each tooth consists of three portions: the *crown*, or *body*, projecting above the gum; the *root*, or *fang*, entirely concealed within the alveolus; and the *neck*, the constricted portion, between the root and crown.

The *surfaces* of a tooth are named thus: that which looks toward the lips is the *labial*; that toward the tongue is the *lingual*; that toward the mesial line, *proximal*; that away from the same, *distal*; that toward the cheek, the *buccal* surface. This applies to the roots as well as to the crowns of teeth.

FIG. 468.—Permanent teeth. Right side (Burchard).

The *roots of the teeth* are firmly implanted within the alveoli (Fig. 472); these depressions are lined with periosteum (the pericementum) which is reflected on to the tooth at the point of the root and covers it as far as the neck. At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Permanent Teeth (Figs. 469 and 470).

The *incisors*, or cutting teeth, are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.

The *crown* is directed almost vertically and is spade-like in form ; it has the form of a truncated cone whose top has been compressed into a sharp horizontal cutting edge. Before being subjected to attrition this edge presents three small elevations. The *labial* surface is convex, and marked by three longitudinal ridges extending from the edge tubercles toward the neck of the tooth. The *lingual* surface is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the *cingulum* or *basal ridge*.

The *mesial* and *distal* surfaces are triangular, the apex of the triangle at the cutting edge.

The *neck* of the tooth is constricted.

The *root* is long, single, and has the form of a transversely flattened cone, thicker before than behind. The root may be curved.

The *incisors* of the *upper jaw* are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the laterals. They are directed obliquely downward and forward.

The *incisors* of the *lower jaw* are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the

teeth. The roots of these teeth are flattened laterally.

The *canine teeth* (*cuspidati*) are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and cause well-marked prominence of the process at the places of insertion.

The *crown* is large, of spear-head, form and its very convex labial surface is marked by three longitudinal ridges. The concave labial surface is also marked by three ridges which unite at a basal ridge. The point or cusp is longer than in the other teeth, and is the point of division between a short mesial and a long distal cutting edge.

The *root* is oval or elliptical in transverse section, and is longer and more prominent than the roots of the incisors.

The *upper canines* or *cuspid*s (vulgarly called the eye teeth) are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The *lower canines* (vulgarly called the stomach teeth) have the general form of the upper cuspid, but their lingual surfaces are much more flattened, owing to the

absence of the elevations marking the upper. Their roots are more flattened and may be bifid at their apices.

The *bicuspid teeth* (*premolars*) are eight in number, four in each jaw ; they are placed distal to the cuspid teeth, two upon each side. They are double cuspid in form.

The *crown* is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspids are not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—*i. e.* it is usually tricuspid.

The *necks* of the teeth are oval ; the roots are laterally compressed, that of the

FIG. 469.—Right half of upper jaw (from below), with the corresponding teeth. The letters and numbers point to the classes of teeth and the numbers in classes.

FIG. 470.—Right half of lower jaw, with the corresponding teeth. The letter and numbers point to the various cusps or their modifications on the different teeth (Burchard).

first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series.

The **molar teeth** (*multicuspidati*; or grinders) are the largest teeth of the denture. They are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The *crowns* are cuboidal in form, are convex buccally and lingually; they are flattened mesially and distally. They are formed by the fusion of three primitive cuspids in the upper and four in the lower. To these are added in the first and second upper molars a disto-lingual tubercle, and in the first and third molars of the lower jaw a disto-buccal tubercle. The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form.

The *roots* of the upper molars are three in number—one large lingual and two smaller buccal roots. In the lower, two roots are found, a mesial and a distal, each of which is much flattened from before backward.

The *first molar teeth* are the largest of the dental series: they have four cusps on the upper and five in the lower—three buccal and two lingual.

The *second molars* are smaller; the crown of the upper is compressed until the disto-lingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle.

The *third molars* are called the wisdom teeth (*dentes sapientiae*) from their late eruption: they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together and curve backward.

Temporary Teeth (Figs. 467 and 471).

The **temporary** or **milk teeth** are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The hinder of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

FIG. 471.—Deciduous teeth. Lingual view.

Arrangement of the Teeth.¹

The human teeth are arranged in two parabolic arches, the upper arch being larger, its teeth overlapping the lower. The average distance between the centres of the condyles of the inferior maxillary bones is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle indicated is included in it; the range of size is between $3\frac{1}{2}$ "– $4\frac{1}{2}$ ".

Owing to the smaller sizes of the lower incisors, the teeth of the lower jaw are each one half a tooth in advance of its upper fellow, so that each tooth of the dental series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 472, 473).

The grinding faces of the upper bicuspids and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve,

¹ After Dr. W. G. A. Bonwill.

the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

FIG. 472.—View of teeth *in situ*, with the external plates of the alveolar processes removed (Cryer).

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average 35° from the horizontal plane.¹

When the lower jaw is advanced until the cutting edges of the incisors are in contact, the jaws are separated, but as the highest point of the lower arch, its third molar advances, it meets and rests upon a high point, second molar of the upper arch, and thus undue strain of the incisors is obviated.

In the lateral movements of the mandible but on one side is ineffective action at one time; the oblique positions of the cusps of the opposite teeth are such

FIG. 473.—Front and side views of the teeth and jaws.

that when either side is in action the other is balanced at two or more points.

¹ W. E. Walker, *Dental Cosmos*, 1896.

There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the inferior maxilla, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before behind, and have a preponderance of the direct over the oblique muscles of mastication, and *vice versa*; teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the heads of the inferior maxilla.

Structure of the Teeth.

The Dental Pulp.—A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth. Processes of the chamber pass from its body, one for each root and down each root, and open at

FIG. 474.—Vertical section of a molar tooth.

the apex by a minute orifice, the apical foramen. This cavity is known as the pulp-chamber, the minute canals the pulp-canals. The cavity contains a soft, vascular, and sensitive organ called the dental pulp. It is made up of myxomatous tissues, and contains numerous blood-vessels and nerves, which enter by way of the apical foramina. It does not possess lymphatics. The periphery of the pulp is bounded by a layer of cells arranged like columnar epithelium, each cell sending one or more branched processes through the basic substance of the dentine. These are the dentine-forming cells, the odontoblasts of Waldeyer. The blood-vessels break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve-fibrils break up into numberless non-medullary filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts.

The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillæ are in the direction of the axis of the root.

The section will exhibit three hard tissues in a tooth, one forming the greater mass of the tooth; hence its name *dentine* (the ivory). The dentine upon the crown is sheathed by a layer called the enamel; the dentine of the root is enclosed

FIG. 475.—Vertical section of a tooth *in situ* (15 diameters). *c* is placed in the pulp-cavity, opposite the cervix or neck of the tooth; the part above is the crown, that below is the root (fang). 1. in a distinct tissue, the cementum or *crusta petrosa*; both cementum and enamel are thinnest at the neck and thickest upon their distal portions.

The **solid portion** of the tooth consists of three distinct structures—viz. the proper dental substance, which forms the larger portion of the tooth, the *ivory* or *dentine*; a layer which covers the exposed part of the crown, the *enamel*; and a thin layer, which is disposed on the surface of the fang, the *cement* or *crusta petrosa*.

FIG. 476.—Ground section through the root of a human premolar: *D*, dentine; *K*, cement corpuscles; *O*, osteoblasts; *Ep.*, remains of Hertwig's epithelial sheath, 200 diameters; *J*, interglobular spaces (Röse).

The *ivory*, or *dentine* (Fig. 475), forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having *distinct parietes*. They are called the *dentinal tubuli*, and are imbedded in a dense homogeneous substance, the *intertubular tissue*.

The *dentinal tubuli* (Fig. 476) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies: they are vertical in the upper portion of the crown, oblique

toward the lower part of the root, and they are inclined downward. The tubuli, at their commencement, are about $\frac{1}{4500}$ of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the root, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the periphery of the dentine the finer ramifications of the tubuli terminate in a layer of irregular branched spaces which communicate with each other. These are called the *interglobular spaces of Czermak*, or the *granular layer of Tomes* (Fig. 476, *J*). The dentinal tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the processes of the cells of the pulp-tissue already mentioned, and first described by Mr. Tomes and named *Tomes's fibres* or *dentinal fibres*. These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory around the canals there is a tissue which is markedly resistant to the action of acids—the *dentinal sheath of Neumann*.

The *intertubular substance* or *tissue* is translucent, and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubules. These laminae show the method of growth to be by deposition of successive strata of dentine. Fibrils have been found in the matrix of the intertubular substance, and are probably continuous with the dentinal fibres of Tomes. In a *dry* tooth a

section of dentine often displays a series of lines—the *incremental lines of Salter*—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line; (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the *interglobular spaces* already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal tubules.

Chemical Composition.—According to Bérzelius and Bibra, dentine consists of 28 parts of animal and 72 of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate with calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The **enamel** is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms. They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. These fibres are directed vertically on the summit of the crown,

FIG. 477.—Enamel prisms (350 diameters). A. Fragments and single fibres of the enamel isolated by the action of hydrochloric acid. B. Surface of a small fragment of enamel, showing the hexagonal ends of the fibres.

horizontally at the sides; they are about the $\frac{1}{5500}$ of an inch in diameter, and pursue a more or less wavy course. Each enamel rod is crossed by a series of dark transverse lines, which mark the mode of the formation of the rods (Fig. 477). Another series of lines, having a brown appearance, and denominated the *parallel striæ of Retzius*, or the *colored lines*, are seen on a section of the enamel. These lines are concentric and cross the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 475).

Numerous minute interstices intervene between the enamel-fibres near their dentinal surface. It is noted in rare cases that the dentinal fibres penetrate a certain distance between the rods of the enamel. No nutritive canals exist in the enamel.

Chemical Composition.—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists

of the phosphate with the carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The **cortical substance**, or **cementum** (*crusta petrosa*), is disposed as a thin layer on the roots of the teeth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunæ and canaliculi which characterize true bone; the lacunæ placed near the surface have the canaliculi radiating from the side of the lacunæ toward the periodontal membrane, *dental periosteum*, and those more deeply placed join with adjacent dentinal tubuli. In the thicker portions of the *crusta petrosa* the lamellæ and Haversian canals peculiar to bone are also occasionally found.

As age advances the cement increases in thickness, and gives rise to those bony growths, or *exostoses*, so common in the teeth of the aged; the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (*osteo-dentine*, Owen; *secondary dentine*, Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

Development of the Teeth.

The teeth are an evolution from the dermoid system, and not of the bony skeleton: they are developed from two of the blastodermic layers, the epiblast and mesoblast. From the former the enamel is developed, from the latter the dental pulp, dentine, cementum, and pericementum. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth-formation in the human embryo is observed in about the seventh week. The mucous membrane covering the embryonic jaws is seen to rise as a longitudinal ridge along the summit of each jaw.¹ A transverse section through the jaws will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer: a corresponding epithelial growth is seen to sink as a band into the mesoblastic tissue beneath. The local cell-activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the inner (toward the tongue) edge of the lamina epithelial cords are given off, ten in number, one for each temporary tooth.

The growth of each cord continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior by swollen mature cells. The ingrowing bulb is now seen to flatten upon its lower surface, as though it had met with an outlined resistance from the mesoblastic tissue beneath. The epithelial ingrowth assumes the general form of the several teeth; it is the enamel-organ of the tooth (Fig. 478). At this period the mesoblastic tissue around each enamel-organ is seen to become differentiated into fibrous tissue surrounding the enamel-organs, but at some distance from them. Islets of bone are also seen to be forming the beginning of the bony maxillæ.

The indentation of the base of the enamel-organ continues until it assumes the form of the future teeth. The cells bounding the organ assume a cylindrical form; the cells of the interior become much expanded, irregular in size and form.

The mesoblastic tissue underlying the enamel-organ is much condensed; evidences of cellular differentiation and a vascular system appear. Bone continues to develop until all of the tooth-follicles are embraced in a gutter of bone. From the lingual side of the cords of the temporary teeth epithelial buds are given off, which sink into the mesoblastic tissue and form the enamel-organs of the permanent teeth. The condensation of fibrous tissue continues until each embryonic tooth is enveloped in a sac, the dental sac; this, together with all of its contents, is called the dental follicle.

The cells of the enamel-organ now undergo a series of differentiations: the inner layer is arranged as columnar epithelium, and is called the ameloblastic or

¹ The maxillary rampart of Kolliker Waldeyer.

enamel-forming layer (Figs. 479 and 480). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of

FIG. 478.—Diagram of method of development of the teeth. 1. Early stage. 4. Later stage. 2, 3. Intermediate stages. *s*. Common dental germ. *o*. Special dental germ (milk). *o'*. Special dental germ (permanent). *p*. Papilla. *e*. Dental furrow. (Gegenbaur.)

their appearance when seen in section this portion of the organ is called the stellate reticulum (the enamel-jelly). The layer of cells immediately contiguous to the ameloblasts form a layer called the stratum intermedium (Fig. 480A—D).

The enclosed mesoblastic papilla (the future dental pulp) has its peripheral cells differentiated into columnar bodies disposed as a layer, each cell having a large

FIG. 479.—Vertical section of the inferior maxilla of an early human fetus. (Magnified 25 diameters.)

nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood-supply. The bony alveolar walls are well outlined, and evidences of a periosteum appear (Figs. 479 and 480).

Development of Enamel.—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calco-globulin), the basis of all the calcified tissues. At the ends of the ameloblasts, next to the dentine, the secretion calco-globulin is deposited, and into the plastic mass the enamel-globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.¹

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum now appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular

¹ J. L. Williams, *Dental Cosmos*, 1896.

globules, and irregular masses of it extruded as cementing substance. The deposition continues until the enamel-cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel-

rods. At the completion of amelification the ameloblasts are partially calcified and form the *cuticula dentis* or Nasmyth's membrane.

Formation of Dentine.—The layer of columnar cells bounding the periphery of the pulp (the odontoblasts) are in apposition with a plexus of capillary vessels (Fig. 480, A). Each cell is a secreting body which selects the material for dentine-building. Against the layer of ameloblasts covering the dental papilla the odontoblasts deposit globules of the calcium albuminate, and, receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit (Tomes's fibres). The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue. The layer of formative cells remains constant.

Formation of Cementum.—Hertwig asserts that the epithelial edge of the enamel-organ formed by the inner and outer epithelial layers of the organ grows downward, or rather the developing tooth grows upward until the future root-form of the tooth is outlined by a double layer of epithelial cells (the root-sheath of Hertwig). The growth of alveolar process is synchronous.

Upon the pulp side of the sheath a layer of odontoblasts is developed; upon the outer side the fibrous encasement becomes closely attached to the sheath and a layer of osteogenetic cells (cementoblasts) is differentiated. The growth of the dentine of the root is the same as in the crown. The epithelial sheath undergoes atrophic changes, leaving epithelial whorls which remain in the pericementum. The cementum is developed as subperiosteal bone. The cementum over the apex of the root is not formed until after the eruption of the tooth.

Formation of Alveoli.—By the time the crowns of the teeth have formed, each

FIG. 481.—Part of section of developing tooth of young rat, showing the mode of deposition of the dentine (highly magnified). a. Outer layer of fully-calcified dentine. b. is enclosed in a locus of bone which has developed around it and at some distance from it; the locus is open at the top toward the gums, where it is closed by fibrous tissue; the developing permanent tooth is contained in the same locus, but is later separated from the temporary tooth by a growth of bone. The alveolar process is not completed until after the eruption of the teeth. During eruption that portion of the process overlying the crown undergoes absorption, and as soon as the immature tooth has erupted the alveolar process is developed about the root, whose formation is also completed after eruption.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number: these are the *successional permanent teeth*; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the *superadded permanent teeth*. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicusps of the permanent set.

The development of the *successional permanent teeth*—the ten anterior ones in either jaw—will be first considered. As already stated, the germ of each milk tooth is a special thickening of the “free” edge of the common dental germ or dental lamina. In like manner is formed the special dental germ of each of the successional permanent teeth. But these thickenings are not at the “free” edge of the dental lamina, but occur behind and lateral to each of the milk-tooth germs (Fig. 478). There are ten of these, and they appear in order, about the sixteenth week, on each side, the central incisor germs being the first.

These special dental germs now go through the same transformations (and become enamel-organs) as were described in connection with those of the milk teeth; that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become flask-shaped, form an expansion of their distal extremity, and finally meet a papilla, which has been formed in the mesoblast, just in the same manner as was the case in the temporary teeth. The apex of the papilla indentates the dental germ, which encloses it, and forming a cap for it, undergoes analogous changes to those described in the development of the milk teeth, and becomes converted into the enamel, whilst the papilla forms the dentine, of the permanent tooth. In its development it becomes enclosed in a dentinal sac which adheres to the *back* of the sac of the temporary tooth. The sac of each permanent tooth is also connected with the fibrous tissue of the gum by a slender band or *gubernaculum*, which passes to the margin of the jaw behind the corresponding milk tooth (see above).

The *superadded permanent teeth*—three on each side in each jaw—arise from successive extensions backward—*i. e.* along the line of the jaw—of the common dental germ from the back part of the special dental germ of the immediately preceding tooth. During the fourth month or seventeenth week, in that portion of the common dental germ which lies behind—*i. e.* lateral to the special dental germ of the last temporary molar tooth, and which has hitherto remained unaltered, there is developed the special dental germ of the first permanent molar into which a papilla projects. In a similar manner, about the fourth month after birth the second molar is formed, and about the third year the third molar.

Eruption.—When the calcification of the different tissues of the *milk* tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, its eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dentinal sacs, at first fibrous in structure, ossify and thus form the loculi or alveoli; these firmly embrace the necks of the teeth and afford them a solid basis.

Previous to the *permanent teeth* penetrating the gum, the bony partitions which separate their sacs from the deciduous teeth are absorbed, the roots of the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called *odontoclasts*, which are developed at the time in the neighborhood of the root, and the permanent teeth become placed under the loose crown of the deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth (Fig. 482).

FIG. 482.—The milk-teeth in a child of about four years. The permanent teeth are seen in their alveoli. (Cryer.)

Calcification of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and cuspid, about six months after birth; the bicuspid, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The *eruption of the temporary teeth* commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes)—

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 “
Lower lateral incisors and first molars	15 to 21 “
Canines	16 to 20 “
Second molars	20 to 24 “

The *eruption of the permanent teeth* takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

6½ years, first molars.	10th year, second bicuspid.
7th year, two middle incisors.	11th to 12th year, canine.
8th year, two lateral incisors.	12th to 13th year, second molars.
9th year, first bicuspid.	17th to 21st year, third molars.

THE PALATE.

The **palate** forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The **hard palate** is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent. Along the middle line is a linear ridge or raphé, which terminates anteriorly in a small papilla corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. On either side and in front of the raphé the mucous membrane is thick, pale in color, and corrugated; behind, it is thin, smooth, and of a deeper color: it is covered with squamous epithelium, and furnished with numerous glands (palatal glands), which lie between the mucous membrane and the surface of the bone.

The **soft palate** (*velum pendulum palati*) is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (*i. e.* relaxed and pendent) its anterior surface is concave, continuous with the roof of the mouth, and marked by a median ridge or raphe, which indicates its original separation into two lateral halves. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free.

Hanging from the middle of its lower border is a small, conical-shaped pendulous process, the *uvula*, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the *arches*, or *pillars of the soft palate*, or *pillars of the fauces*.

The *anterior pillars* run downward, outward, and forward to the sides of the base of the tongue, and are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The *posterior pillars* are nearer to each other and larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the tonsil is lodged.

The space left between the arches of the palate on the two sides is called the *isthmus of the fauces*. It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side, by the pillars of the fauces and the tonsil.

The *mucous membrane of the soft palate* is thin, and covered with squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where it is columnar and ciliated.¹ Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

The *aponeurosis of the soft palate* is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendon of the Tensor palati muscle.

¹ According to Klein, the mucous membrane on the nasal surface of the soft palate in the fœtus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.

The *muscles of the soft palate* are five on each side: the Levator palati, Tensor palati, Azygos uvulæ, Palato-glossus, and Palato-pharyngeus (see page 329). The following is the relative position of these structures in a dissection of the soft palate from the posterior or nasal to the anterior or oral surface: Immediately beneath the nasal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. Beneath this is the Azygos uvulæ, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the Levator palati, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding round the hamular process, expands into a broad aponeurosis in the soft palate, anterior to the other muscles which have been enumerated. Finally, we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The *Tonsils* (*amygdalæ*) are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. A recess, the *fossa supra-tonsillaris*, may be seen, directed upward and backward above the tonsil. His regards this as the remains of the lower part of the second visceral cleft. It is covered by a fold of mucous membrane termed the *plica triangularis*. Externally the tonsil is in relation with the inner surface of the Superior constrictor, to the outer side of which is the Internal pterygoid muscle. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (20 to 25 mm.) distant from it. It corresponds to the angle of the lower jaw. Its *inner surface* presents from twelve to fifteen orifices, leading into small recesses, from which numerous follicles branch out into the substance of the gland. These follicles are lined by a continuation of the mucous membrane of the pharynx, covered with epithelium; around each follicle is a layer of closed capsules imbedded in the submucous tissue. These capsules are analogous to those of Peyer's glands, consisting of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion. Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the deep cervical glands in the upper part of the neck, which frequently become enlarged in affections of these organs.

The *arteries* supplying the tonsil are the dorsalis linguæ from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The *veins* terminate in the tonsillar plexus, on the outer side of the tonsil.

The *nerves* are derived from Meckel's ganglion and from the glosso-pharyngeal.

THE SALIVARY GLANDS (Fig. 483).

The principal salivary glands communicating with the mouth and pouring their secretion into its cavity are the parotid, submaxillary, and sublingual.

The *parotid gland*, so called from being placed near the ear (*παρά*, near; *ὠτός*, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between it and the mastoid process: anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the two muscles.

Its *anterior surface* is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and superficial to the ramus over the Masseter muscle. Its *outer surface*, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its *inner surface* extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the external carotid artery, giving off its three terminal branches: the posterior auricular artery emerges from the gland behind; the temporal artery above; the transverse facial, a branch of the temporal, in front;

FIG. 483.—The salivary glands.

and the internal maxillary winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the temporal and internal maxillary veins; a branch, connecting this trunk with the internal jugular, also passes through the gland. It is also traversed by the facial nerve and its branches, which emerge at its anterior border; branches of the great auricular nerve pierce the gland to join the facial, and the auriculo-temporal branch of the inferior maxillary nerve emerges from the upper part of the gland. The internal carotid artery and internal jugular vein lie close to its deep surface.

The duct of the parotid gland (*Stenson's*) is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator and mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar tooth of the upper jaw. While crossing the Masseter it receives the duct of a small

detached portion of the gland, *socia parotidis*, which occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Structure.—The parotid duct is dense, of considerable thickness, and its canal about the size of a crowquill, but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size; it consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger's breadth below the zygoma; that is, from the lower margin of the concha to midway between the free margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The *veins* empty themselves into the external jugular through some of its tributaries. The *lymphatics* terminate in the superficial and deep cervical

FIG. 484.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)

glands, passing in their course through two or three lymphatic glands placed on the surface and in the substance of the parotid. The *nerves* are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculo-temporal, and great auricular nerves.

It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion (which see). At all events, in some of the lower animals this has been proved experimentally to be the case.

The **submaxillary gland** is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms (8–10 grammes). It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of the bone, and lies upon the Mylo-hyoid, Hyo-glossus, and Stylo-glossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric; behind, it is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies imbedded in a groove in its posterior and upper border.

The **duct of the submaxillary gland** (*Wharton's*) is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylo-hyoid muscle, and passes forward, and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyo-glossus muscles, then between the sublingual gland and the Genio-hyo-glossus, and opens by a narrow orifice on the

summit of a small papilla at the side of the frænum linguæ. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.

Vessels and Nerves.—The *arteries* supplying the submaxillary gland are branches of the facial and lingual. Its *veins* follow the course of the arteries. The *nerves* are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and lingual branch of the inferior maxillary, sometimes from the mylo-hyoid branch of the inferior dental, and from the sympathetic.

The **sublingual gland** is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frænum linguæ, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, *above*, with the mucous membrane; *below*, with the Mylo-hyoid muscle; *in front*, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; and *internally*, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its excretory ducts (*ducts of Rivinus*), from eight to twenty in number; some join Wharton's duct; others open separately into the mouth, on the elevated crest of mucous membrane caused by the projection of the gland, on either side of the frænum linguæ. One or more join to form a tube which opens into the Whartonian duct; this is called the *duct of Bartholin*.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands.—The salivary are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, "branching frequently in a tree-like manner," the branches terminating in dilated ends or alveoli, on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane which is continuous with the membrana propria of the duct. It presents a peculiar reticulated structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid which contains mucin, and has therefore been named the *mucous*, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and has been named *serous* or *albuminous*. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The **cells in the mucous alveoli** are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process, which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying between the cells and the membrana propria of the alveolus. They are termed the *crescents of Gianuzzi* or the *demilunes of Heidenhain* (Fig. 484), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous Alveoli.—In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature imbedded in a closely reticulated protoplasm. The ducts which originate out of the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cell next the basement-membrane is finely striated. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the intervalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve-fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; they are to be found in the submaxillary, but not in the parotid.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papillæ, and also along its margins as far forward as the apex.¹ Others lie around and in the tonsil between its crypts, and a large number are present in the soft palate. These glands are of the ordinary compound racemose type.

Surface Form.—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Mongolian tribes, where the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphe which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillæ; the posterior third smooth and tuberculated, covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillæ which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the *frænum linguae*, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this frænum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or

¹ It has been shown by Ebner that many of these glands open into the trenches around the circumvallate papillæ, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.

less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frænum, the ranine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frænum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the frænum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton's ducts, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the *fræna*; these are not so large as the frænum linguæ. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. There are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, "the throat:" this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting downward from the middle of its lower border is a conical-shaped projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the tonsil. The extirpation of this body is not unattended with danger of hemorrhage. Dr. Weir has stated that he believes that when hemorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the Pterygo-maxillary ligament, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the lingual (gustatory) nerve, where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 735). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphylorrhaphy. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the jaw can be felt, and is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebræ may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the naso-pharynx ascertained.

THE PHARYNX.

The **pharynx** is that part of the alimentary canal which is placed behind the nose, mouth, and larynx. It is a musculo-membranous tube, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the level of the cricoid cartilage in front and that of the intervertebral disk between the fifth and sixth cervical vertebræ behind.

The pharynx is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest point, at its termination in the œsophagus. It is limited, *above*, by the body of the sphenoid and basilar process of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longi colli and Recti capitis antici muscles; *anteriorly*, it is incomplete, and is attached in succession to the internal pterygoid plate, the pterygo-maxillary ligament, the lower jaw, the tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles.

It has seven openings communicating with it—the two posterior nares, the two Eustachian tubes, the mouth, larynx, and œsophagus.

The pharynx may be subdivided from above downward into three parts, nasal, oral, and laryngeal. The nasal part of the pharynx (*pars nasalis*) or naso-pharynx lies behind the nose and above the level of the soft palate: it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the choanæ with the nasal fossæ. On its lateral wall is the pharyngeal orifice of the Eustachian tube, which presents the appearance of a vertical cleft bounded behind by a firm prominence, the *cushion*, caused by the inner extremity of the cartilage of the tube impinging on the deep surface of the mucous membrane. A vertical fold of mucous membrane, the *plica salpingo-pharyngea*, stretches from the lower part of the cushion to the pharynx; it contains the Salpingo-pharyngeus muscle. A second and smaller mucous fold may be seen stretching from the upper part of the cushion to the palate, the *plica salpingo-palatina*. Behind the orifice of the Eustachian tube is a deep recess, the *fossa of Rosenmüller*, which represents the remains of the upper part of the second branchial cleft.

The oral part of the pharynx (*pars oralis*) reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two pillars of the fauces, is the tonsil.

The laryngeal part of the pharynx (*pars laryngea*) reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the œsophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the aryteno-epiglottidean folds. On either side of the laryngeal orifice is a recess, termed the *sinus pyriformis*; it is bounded internally by the aryteno-epiglottidean fold, externally by the thyroid cartilage and thyro-hyoid membrane.

Structure.—The pharynx is composed of three coats—mucous, fibrous, and muscular.

The *pharyngeal aponeurosis*, or *fibrous coat*, is situated between the mucous and muscular layers. It is thick above, where the muscular fibres are wanting, and is firmly connected to the basilar process of the occipital and petrous portion of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a median raphe, which gives attachment to the Constrictor muscles of the pharynx.

The *mucous coat* is continuous with that lining the Eustachian tubes, the nares, the mouth and the larynx. In the naso-pharynx it is covered by columnar ciliated epithelium; in the buccal and laryngeal portions the epithelium is of the squamous variety. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts or

recesses, the walls of which are surrounded by lymphoid tissue similar to what is found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the *pharyngeal tonsil*. Above this in the middle line is an irregular, flask-shaped depression of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the *bursa pharyngea*, and was regarded by Luschka as the remains of the diverticulum, which is concerned in the development of the anterior lobe of the pituitary body. Other anatomists believe that it is connected with the formation of the pharyngeal tonsils.

The *muscular coat* has been already described (page 328).

Surgical Anatomy.—The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the œsophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as retro-pharyngeal abscess. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuration of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by a gumma or by acute pharyngitis. In these cases the pus may be easily evacuated by an incision, with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy; the abscess can be felt bulging at the side of the neck and merely requires an incision for its relief, but this is not always so, and then an incision should be made along the posterior border of the Sterno-mastoid and the deep fascia divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of sinus forceps are now inserted along the director and the opening into the cavity dilated.

Foreign bodies not infrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about six inches.

THE ŒSOPHAGUS.

The *œsophagus*, or *gullet*, is a muscular canal, about nine inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae, descends along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach opposite the tenth dorsal vertebra or the intervertebral disk between the tenth and eleventh dorsal vertebrae. The general direction of the œsophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to the œsophageal opening of the Diaphragm. The œsophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

Relations.—*In the neck* the œsophagus is in relation, *in front*, with the trachea, and at the lower part of the neck, where it projects to the left side, with the thyroid gland and thoracic duct; *behind*, it rests upon the vertebral column and Longi colli muscles; *on each side*, it is in relation with the common carotid artery (especially the left, as it inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax, it is at first situated a little to the left of the median line; it then passes behind the aortic arch, separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, *in front*, with the trachea, the arch of the aorta, the left carotid and left subclavian arteries, which incline toward its left side, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longi colli muscles, the right intercostal arteries, and the vena azygos minor; and below, near the Diaphragm, upon the front of the aorta; *laterally*, it comes in contact with both pleuræ, especially with the left pleura above and the right pleura below: it overlaps the vena azygos major, which lies on its right side, while the descending aorta is placed on its left side. The pneumogastric nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it; the two nerves uniting to form a plexus (the *plexus gulæ*) around the tube.

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the œsophagus; higher up, it is placed behind it, and, crossing about the level of the fourth dorsal vertebra, is continued upward on its left side.

Structure.—The œsophagus has three coats—an external or muscular; a middle or areolar; and an internal or mucous coat.

The *muscular coat* is composed of two planes of fibres of considerable thickness, an external longitudinal and an internal circular.

The *longitudinal fibres* are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor: as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Cunningham as passing between the œsophagus and the left pleura, where it covers the thoracic aorta (almost always), or the root of the left bronchus (usually), or the back of the pericardium, as well as other still more rare accessory fibres. In Fig. 485, taken from a dissection in the Museum of the Royal College of Surgeons of England, several of these accessory slips may be seen passing from the œsophagus to the pleura, and two slips to the back of the trachea just above its bifurcation.

The *circular fibres* are continuous above with the Inferior constrictor; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part.

The muscular fibres in the upper part of the œsophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre.

The *areolar coat* connects loosely the mucous and muscular coats.

The *mucous coat* is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papillæ, and it is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the *muscularis mucosæ*. At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are numerous small compound racemose glands scattered throughout the tube; they are lodged in the submucous tissue, and open upon the surface by a long excretory duct. They are most numerous at the lower part of the tube, where they form a ring round the cardiac orifice.

Vessels of the Œsophagus.—The arteries supplying the œsophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta, and from the gastric branch of the cœliac

axis, and from the left inferior phrenic of the abdominal aorta. They have for the most part a longitudinal direction.

Nerves of the Œsophagus.—The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Surgical Anatomy.—The relations of the Œsophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of stricture of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the Œsophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the Œsophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

The student should also remember that obstruction of the Œsophagus, and consequent symptoms of stricture, are occasionally produced by an aneurism of some part of the aorta pressing upon this tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left fore finger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onward, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the Œsophagus which can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the Œsophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of Œsophagotomy is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length, should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin, Platysma, and deep fascia. The edges of the wound being separated, the Omo-hyoid muscle should, if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, must be drawn outward, and retained in that position by retractors: the Œsophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The Œsophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new growths or aneurism, etc.

The different forms of stricture are: (1) the spasmodic, usually occurring in nervous women, and intermittent in character, so that the dysphagia is not constant; (2) fibrous, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epitheliomatous in its nature. This is situated generally either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice, but is also occasionally found at that part of the tube where it is crossed by the left bronchus.

The operation of Œsophagostomy has occasionally been performed in cases where the stricture in the Œsophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better, if any operative interference is undertaken, to perform gastrostomy. The operation is performed in the same manner as Œsophagotomy, but the edges of the opening in the Œsophagus are stitched to the skin incision.

FIG. 485.—Accessory muscular fibres between the Œsophagus and pleura, and Œsophagus and trachea. (From a preparation in the Museum of the Royal College of Surgeons of England.)

FIG. 486.—Topography of thoracic and abdominal viscera.

THE ABDOMEN.

The **Abdomen** is the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward: the upper one being formed by the under surface of the Diaphragm, the lower by the upper concave surface of the Levatores ani. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the *abdomen proper*; and a lower and smaller part, the *pelvis*. These two cavities are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The space is wider above than below, and measures more in the vertical than in the transverse diameter.

The abdomen proper differs from the other great cavities of the body in being bounded for the most part by muscles and fasciæ, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex. In the adult male, with moderate distention of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

Boundaries.—The boundary between the thorax and abdomen is the Diaphragm. This muscle forms a dome over the abdomen, and the cavity extends high into the bony thorax, reaching to the level of the junction of the fourth costal cartilage with the sternum. The lower end of the abdomen is limited by the structures which clothe the inner surface of the bony pelvis, principally the Levatores ani and Coccygei muscles on either side. These muscles are sometimes termed the *Diaphragm of the pelvis*. The abdomen proper is bounded *in front* and *at the sides* by the lower ribs, the abdominal muscles, and the venter ilii; *behind*, by the vertebral column and the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the brim of the pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named, according to the part which it covers.

The abdomen contains the greater part of the alimentary canal; some of the accessory organs to digestion, viz., the liver and pancreas; the spleen, the kidneys, and suprarenal capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the *peritoneum*.

The *apertures* found in the walls of the abdomen, for the transmission of structures to or from it, are, the *umbilicus*, for the transmission (in the fœtus) of the umbilical vessels; the *caval opening* in the Diaphragm, for the transmission of the inferior vena cava; the *aortic opening*, for the passage of the aorta, vena azygos major, and thoracic duct; and the *œsophageal opening*, for the œsophagus and pneumogastric nerves. *Below*, there are two apertures on each side: one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions. Thus, if two circular lines are drawn round the body, the one through the extremities of the ninth ribs where they join their costal cartilages, and the other through the highest point of the crests of the ilia, the abdominal cavity is divided into three zones—an upper, a middle, and a lower. If two parallel lines are drawn perpendicularly upward from the centre of Poupart's ligament, each of these zones is subdivided into three parts—a middle and two lateral.¹

¹ Anatomists are far from agreed as to the best method of subdividing the abdominal cavity. Cunningham suggests that the lower line should encircle the body on a level with the highest point of the iliac crest, as seen from the front—a point corresponding with a prominent tubercle on the outer lip of the iliac crest about two inches behind the anterior superior spine. Addison,¹ in a careful analysis of the abdominal viscera in forty subjects, adopts the following lines: (1) a median,

¹ *Journal of Anatomy and Physiology*, vols. xxxiv. and xxxv.

The middle region of the upper zone is called the *epigastric* (ἐπί, *over*; γαστήρ, *the stomach*); and the two lateral regions, the *right* and *left hypochondriac* (ὑπό, *under*; χονδροί, *the cartilages*). The central region of the middle zone is the *umbilical*; and the two lateral regions, the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric* or *pubic region*; and the lateral regions are the *right* and *left inguinal* or *iliac*. The viscera contained in these different regions are the following (Fig. 487).

Right Hypochondriac.

The greater part of right lobe of the liver, the hepatic flexure of the colon, and part of the right kidney.

Epigastric Region.

The greater part of the stomach, including both cardiac and pyloric orifices, the left lobe and part of the right lobe of the liver and the gall-bladder, the pancreas, the duodenum, the suprarenal capsules, and parts of the kidneys.

Left Hypochondriac.

The fundus of the stomach, the spleen and extremity of the pancreas, the splenic flexure of the colon, and part of the left kidney.

Right Lumbar.

Ascending colon, part of the right kidney, and some convolutions of the small intestines.

Umbilical Region.

The transverse colon, part of the great omentum and mesentery, transverse part of the duodenum, and some convolutions of the jejunum and ileum, and part of both kidneys.

Left Lumbar.

Descending colon, part of the omentum, part of the left kidney, and some convolutions of the small intestines.

Right Inguinal (Iliac).

The cæcum and vermiform appendix.

Hypogastric Region.

Convolutions of the small intestines, the bladder in children, and in adults if distended, and the uterus during pregnancy.

Left Inguinal (Iliac).

Sigmoid flexure of the colon.

If the anterior abdominal wall is reflected in the form of four triangular flaps by means of vertical and transverse incisions—the former from the ensiform cartilage to the symphysis pubis, the latter from flank to flank at the level of the umbilicus—the abdominal or peritoneal cavity is freely opened into and the contained viscera are in part exposed.¹

Above and to the right side is the liver, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line, and reaching for some distance below the level of the ensiform cartilage. Below and to the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the *great omentum*, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera. Below it, however, some of the coils of the small intestine can generally be seen, while in the right and left iliac regions respectively the *cæcum* and the *sigmoid flexure* of the colon are exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project

from symphysis pubis to ensiform cartilage; (2) two lateral lines drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line halfway between the symphysis pubis and the supra-sternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis.

¹ It must be borne in mind that, although the term *abdominal cavity* is used, there is, under normal conditions, only a potential cavity or lymph-space, since the viscera are everywhere in contact with the parietes.

above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or *duodenum*, the point of continuity being marked by a thickened ring which indicates the position of the pyloric valve. The duodenum passes toward the under surface of the liver, and then curving downward, is lost to sight. If, however, the great omentum be thrown upward over the chest, the terminal part of the duodenum will be observed passing across the spine toward the left side, where it becomes continuous with the *coils of the small intestine*. These measure some twenty feet in length, and if followed downward will be seen to end in the right iliac fossa by opening into the *cæcum* or commencement of the *large intestine*. From the cæcum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the *ascending, transverse, and descending parts of the colon*. In the left iliac region it makes still another bend, the *sigmoid flexure*, and then follows the curve of the sacrum as the *rectum*.

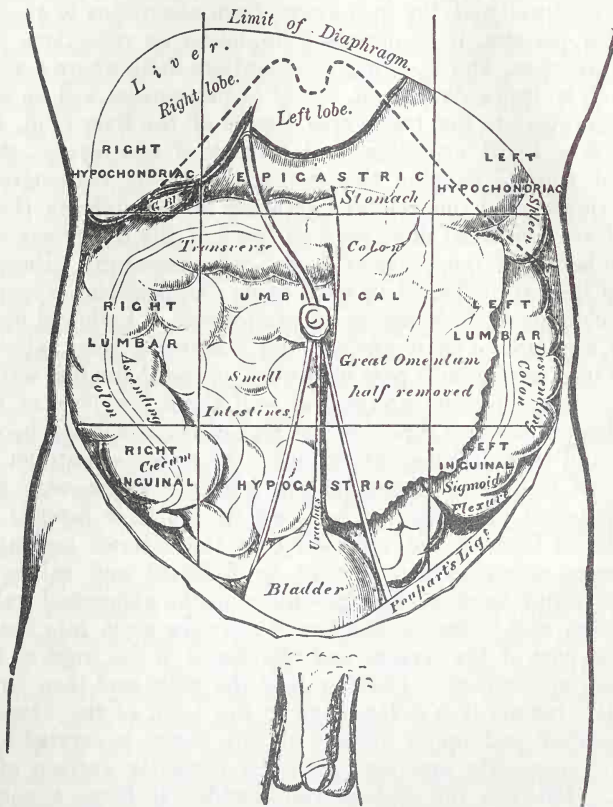

FIG. 487.—The regions of the abdomen and their contents. (Edge of costal cartilages in dotted outline.)

The *spleen* lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side.

The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined and the latter more or less completely covered by a serous membrane, the *peritoneum*.

The Peritoneum.

The peritoneum is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the

peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The former constitutes the *parietal*, the latter the *visceral* part of the peritoneum. The *free surface* of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. Its *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of *areolar tissue* termed the *subserous areolar tissue*. The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and also in the middle line of the abdomen.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement—an arrangement which can only be clearly understood by following the changes which take place in the alimentary canal during its development; and therefore the student is advised to preface his study of the peritoneum by reviewing the chapter dealing with this subject in the section on Embryology.

To trace the continuity of the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its reflections in the vertical and horizontal directions, and in doing so it matters little where a start is made.

If the stomach is drawn downward, a fold of peritoneum will be seen stretching from its lesser curvature to the transverse fissure of the liver (Fig. 488). This is the *gastro-hepatic* or *small omentum*, and consists of two layers; these, on being traced downward, split to envelop the stomach, covering respectively its anterior and posterior surfaces. At the greater curvature of the stomach they again come into contact and are continued downward in front of the transverse colon, forming the anterior two layers of the *great* or *gastro-colic* omentum. Reaching the free edge of this fold they are reflected upward as its two posterior layers, and thus the great omentum consists of four layers of peritoneum. Followed upward the two posterior layers separate so as to enclose the transverse colon, above which they once more come into contact and pass backward to the abdominal wall as the *transverse mesocolon*. Reaching the abdominal wall about the level of the transverse part of the duodenum, the two layers of the transverse mesocolon become separated from each other and take different directions; the upper or anterior layer ascends (ascending layer of transverse mesocolon) in front of the pancreas, and its further course will be followed presently. The lower or posterior layer is carried downward, as the anterior layer of the *mesentery*, by the superior mesenteric vessels to the small intestine, around which it may be followed and subsequently traced upward as the posterior layer of the mesentery to the abdominal wall. From the posterior abdominal wall it sweeps downward over the aorta into the pelvis, where it invests the first part of the rectum and attaches it to the front of the sacrum by a fold termed the *mesorectum*. Leaving first the sides and then the front of the second part of the rectum it is reflected on to the back of the bladder, and, after covering the posterior and upper aspects of this viscus, is carried by the urachus and obliterated hypogastric arteries on to the posterior surface of the anterior abdominal wall. Between the rectum and bladder it forms a pouch, the *recto-vesical pouch*, bounded on each side by a crescentic or *semilunar fold*; the bottom of this pouch is about on a level with the middle of the vesiculæ seminales—i. e., three inches or so from the orifice of the anus. When the bladder is distended the peritoneum is carried up with the expanded viscus, so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of the peritoneal membrane.

In the female the peritoneum is reflected from the rectum on to the upper part of the posterior vaginal wall, forming the *recto-vaginal pouch* or *pouch of Douglas*. It is then carried over the posterior aspect and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, forming here a second but shallower depression, the *utero-vesical pouch*. It

is also reflected from the sides of the uterus to the lateral walls of the pelvis as two expanded folds, the *broad ligaments of the uterus*, in the free margin of each of which can be felt a thickened cord-like structure, the *Fallopian tube*.

On following the parietal peritoneum upward on the back of the anterior abdominal wall it is seen to be reflected around a fibrous band, the *ligamentum teres* or *obliterated umbilical vein*, which reaches from the umbilicus to the under surface of the liver. Here the membrane forms a somewhat triangular fold, the *falciform* or *suspensory ligament* of the liver, which attaches the upper and anterior surfaces of that organ to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the under surface of the anterior part of the Diaphragm and is reflected from it on to the upper surface of the liver as the *anterior* or *superior layer of the coronary ligament*. Covering the upper and anterior surfaces of the liver it is reflected round its sharp margin on to its under surface as far as the transverse fissure, where it is continuous with the anterior layer of the small omentum from which a start was made. The posterior layer of this omentum is carried backward from the transverse fissure over the under surface and Spigelian lobe of the liver, and is then reflected, as the *posterior* or *inferior layer of the coronary ligament*, on to the Diaphragm and is prolonged downward over the pancreas to become continuous with the ascending layer of the transverse mesocolon. Between the two layers of the coronary ligament there is a triangular surface of the liver which is devoid of peritoneum; it is named the *bare area* of the liver, and is attached to the Diaphragm by connective tissue. If, however, the two layers of the coronary ligaments are traced toward the right and left margins of the liver, they approach each other, and, ultimately fusing, they form the right and left lateral ligaments of the liver and attach its right and left lobes respectively to the Diaphragm.

If the small omentum is followed toward the right side it is seen to form a distinct free edge around which its anterior and posterior layers are continuous with each other and between which are situated the portal vein, hepatic artery, and bile-duct. If the finger is introduced behind this free edge, it passes through a somewhat constricted ring, the *foramen of Winslow*. This is the communication between what are termed the greater and lesser sacs of the peritoneum and has the following boundaries: in front, the free edge of the gastro-hepatic omentum with the portal vein, hepatic artery, and bile-duct between its two layers; behind, the vena cava inferior; above, the Spigelian and caudate lobes of the liver; below, the duodenum and the hepatic artery, as the latter passes forward and upward from the cœliac axis.

The *lesser sac of the peritoneum* therefore lies behind the small omentum and has the following dimensions: above, it is limited by the portion of the liver which lies behind the transverse fissure; below, it extends downward into the great omentum, reaching, in the foetus, as far as its free edge; in the adult, however, its vertical extent is limited by adhesions between the layers of the omentum. In front, it is bounded by the small omentum, stomach, and anterior two layers of the great omentum; behind, by the two posterior layers of the great omentum, the transverse colon, and ascending layer of the transverse mesocolon which passes upward in front of the pancreas as far as the posterior surface of the liver. Laterally the lesser sac reaches from the foramen of Winslow on the right side as far as the spleen on the left, where it is limited by the lienorenal ligament. The extent of the lesser sac and its relations to surrounding parts can be definitely made out by tearing through the small omentum and inserting the hand through the opening thus made.

It should be stated that during a considerable part of foetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own—the two posterior layers of the great omentum passing, at this stage, in front of the colon. This condition sometimes persists throughout adult life, but as a rule adhesion occurs between the mesentery and the transverse colon and the posterior layer of the great omentum, with the result that the colon appears to receive

its peritoneal covering by the splitting of the two posterior layers of the latter fold.

In addition to tracing the peritoneum vertically, it is necessary to trace it horizontally. If this is done below the transverse colon, the circle is extremely simple, as it includes only the greater sac of the peritoneum (Fig. 488). Above the level of the transverse colon the arrangement is more complicated, on account of the existence of the two sacs.

Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, the peritoneum covers the internal surface of the abdominal wall almost as far as the anterior border of the Quadratus lumborum muscle; it encloses the cæcum, and is reflected over the sides and anterior surface of the ascending colon, fixing it to the abdominal wall, from which it can be traced over the kidney to the front of the bodies of the vertebræ. It then passes along the mesenteric vessels to invest the small intes-

FIG. 488.—The reflections of the peritoneum, as seen in a vertical section of the abdomen.

tine. and back again to the spine, forming the mesentery, between the layers of which are contained the mesenteric blood-vessels, nerves, lacteals, and glands. Lastly, it passes over the left kidney to the sides and anterior surface of the descending colon, and, reaching the abdominal wall, is continued along it to the middle line of the abdomen.

Above the transverse colon (Fig. 489) the peritoneum can be traced, forming the greater and lesser cavities, and their communication through the foramen of Winslow can be demonstrated. Commencing in the middle line of the abdomen, the membrane may be traced lining its anterior wall, and sending a process backward to encircle the obliterated umbilical vein (the round ligament of the liver), forming the falciform or longitudinal ligament of the liver. Continuing its course

to the right, it is reflected over the front of the upper part of the right kidney, across the vena cava inferior and aorta, and over the left kidney to the hilum of the spleen, forming the anterior layer of the *lieno-renal ligament*, the posterior layer being formed by the termination of the *cul-de-sac* of the greater cavity between the kidney and spleen. From the hilum of the spleen it is reflected to the stomach, forming the posterior layer of the *gastro-splenic omentum*. It covers the posterior surface of the stomach, and from its lesser curvature it passes around the portal vein, hepatic artery, and bile-duct, and back again to the stomach, as the lesser omentum, and thus it forms the anterior boundary of the foramen of Winslow. It now covers the front of the stomach, and upon reaching the cardiac extremity it passes to the hilum of the spleen, forming the anterior layer of the gastro-splenic omentum. From the hilum of the spleen it can be traced over the surface of this organ, to which it gives a serous covering; it is then reflected from the posterior border of the hilum on to the left kidney, forming the posterior layer of the lieno-renal ligament.

FIG. 489.—Transverse section of peritoneum.

Numerous folds, formed by the peritoneum, extend between the various organs or connect them to the parietes. These serve to hold them in position, and at the same time enclose the vessels and nerves proceeding to each part. Some of these folds are called *ligaments*, such as the ligaments of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the *mesenteries*; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called *omenta*.

The **Ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **Omenta** are: the lesser omentum, the great omentum, and the gastro-splenic omentum.

The *lesser omentum* (*gastro-hepatic*) is the duplicature which extends between the transverse fissure of the liver and the lesser curvature of the stomach. It is extremely thin, and consists of two layers of peritoneum: that is, the two layers

covering respectively the anterior and posterior surfaces of the stomach. When these two layers reach the lesser curvature of the stomach, they join together and ascend as the double fold to the transverse fissure of the liver; to the left of this fissure the double fold is attached to the fissure of the ductus venosus as far as the Diaphragm, where the two layers separate to embrace the end of the oesophagus. At the right border the lesser omentum is free, and the two layers of which it is composed are continuous. The anterior layer, which belongs to the greater sac, turns round the hepatic vessels to become continuous with the posterior layer belonging to the lesser one. They here form a free, rounded margin, which contains between its layers the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves—all these structures being enclosed in loose areolar tissue, called *Glisson's capsule*. Between the layers where they are attached to the stomach lie the gastric artery and the pyloric branch of the hepatic, anastomosing with it.

The *great omentum* (*gastro-colic*) is the largest peritoneal fold. It consists of four layers of peritoneum, two of which descend from the stomach, one from its anterior, the other from its posterior surface, and, uniting at its lower border, descend in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the great omentum is continuous with the gastro-splenic omentum: its right border extends as far only as the duodenum. The great omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat subjects accumulates in considerable quantity. Its use appears to be to protect the intestines from the cold, and to facilitate their movement upon each other during their vermicular action. Between its two anterior layers is the anastomosis between the right and left gastro-epiploic arteries.

The *gastro-splenic omentum* is the fold which connects the margins of the hilum of the spleen to the *cul-de-sac* of the stomach, being continuous by its lower border with the great omentum. It contains the *vasa brevia* vessels.

The *Mesenteries* are: the mesentery proper, the transverse mesocolon, the sigmoid mesocolon, and the mesorectum. In addition to these there are sometimes present an ascending and a descending mesocolon.

The *mesentery* (*μέσων έντερον*), so called from being connected to the middle of the cylinder of the small intestine, is the broad fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*, the part connected with the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right sacro-iliac symphysis (Fig. 490). Its intestinal border is much longer; and here its two layers separate so as to enclose the intestine, and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about eight inches. Its *upper border* is continuous with the under surface of the transverse mesocolon: its *lower border*, with the peritoneum covering the cæcum and ascending colon. It serves to retain the small intestines in their position, and contains between its layers the mesenteric vessels and nerves, the lacteal vessels, and mesenteric glands.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively. At the place where the transverse colon turns downwards to form the descending colon, a fold of peritoneum is continued to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the *phreno-colic ligament*; it passes below the spleen, and serves to support this organ, and therefore it has received the second name of *sustentaculum lienis*.

The *transverse mesocolon* is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two ascending or posterior layers of the great omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the spine, where they diverge in front of the duodenum. This fold contains between its layers the vessels which supply the transverse colon.

FIG. 490.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

The *sigmoid mesocolon* is the fold of peritoneum which retains the sigmoid flexure in connection with the left iliac fossa.

The *mesorectum* is the narrow fold which connects the upper part of the rectum with the front of the sacrum. It contains the superior hemorrhoidal vessels.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

Retro-peritoneal fossæ.—In certain parts of the abdominal cavity there are recesses of peritoneum forming *culs-de-sac* or pouches, which are of surgical inter-

est in connection with the possibility of the occurrence of retro-peritoneal hernia. One of these is the lesser sac of the peritoneum, which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses of fossæ may be divided into three groups, viz.: (1) the duodenal fossæ; (2) pericæcal fossæ; and (3) the intersigmoid fossa.

1. *Duodenal Fossæ*.—Moynihan has described no less than nine fossæ as occurring in the neighborhood of the duodenum. Three of these are fairly constant, and are the only ones which require mention. (a) The *inferior duodenal fossa* is the most constant of all the peritoneal fossæ in this region, being present in from 70 to 75 per cent. of cases. It is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. The opening into the fossa is directed upward, and is bounded by a thin sharp fold of peritoneum with a concave margin, called the *inferior duodenal fold*. The tip of the index finger introduced into the fossa under the fold passes some little distance up behind the ascending or fourth portion of the duodenum. (b) The *superior duodenal fossa* is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases. It often coexists with the inferior one, and its orifice looks downward, in the opposite direction to the preceding fossa. It lies to the left of the ascending portion of the duodenum. It is bounded by the free edge of the *superior duodenal fold*, which presents a semilunar margin; to the right it is blended with the peritoneum covering the ascending duodenum, and to the left with the peritoneum covering the perirenal tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. Its depth is 2 cm., and it terminates in the angle formed by the left renal vein crossing the aorta. This fossa is of importance, as it is in relation with the inferior mesenteric vein: that is to say, the vein almost always corresponds to the line of union of the superior duodenal fold with the posterior parietal peritoneum. (c) The *duodeno-jejunal fossa* can be seen by pulling the jejunum downward and to the right, after the transverse colon has been pulled upward. It will appear as an almost circular opening, looking downward and to the right, and bounded by two free borders or folds of peritoneum, the *duodeno-mesocolic ligaments*. The opening admits the little finger into the fossa to the depth of from 2 to 3 cm. The fossa is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa.

2. *Pericæcal Fossæ*.—There are at least three pouches or recesses to be found in the neighborhood of the cæcum, which are termed *pericæcal fossæ*. (1) The *ileo-colic fossa* (superior ileo-cæcal) is formed by a fold of peritoneum, the ileo-colic fold, arching over a branch of the ileo-colic artery, which supplies the ileo-colic junction, and appears to be the direct continuation of the artery. The fossa is a narrow chink situated between the ileo-colic fold in front, and the mesentery of the small intestine, the ileum, and a small portion of the cæcum behind. (2) The *ileo-cæcal fossa* (inferior ileo-cæcal) is situated behind the angle of junction of the ileum and cæcum. It is formed by a fold of peritoneum (the ileo-cæcal fold or bloodless fold of Treves), the upper border of which is attached to the ileum, opposite its mesenteric attachment, and the lower border, passing over the ileo-cæcal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold is sometimes called the ileo-appendicular. Between this fold and the mesentery of the vermiform appendix is the ileo-cæcal fossa. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ileo-cæcal fold, and behind by the upper part of the mesentery of the appendix. (3) The *subcæcal fossa* (retro-cæcal) is situated immediately behind the cæcum, which has to be raised to bring it into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger, and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. It is bounded and formed by two folds: one, the *parieto-colic*,

which is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the postero-external aspect of the colon; and the other, *mesenterico-parietal*, which is in reality the insertion of the mesentery into the iliac fossa. In some instances the subcæcal fossa is double.

3. The *Intersigmoid fossa* is constant in the foetus and during infancy, but disappears in a certain percentage of cases as age advances. Upon drawing the sigmoid flexure upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoidea, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Any of these fossæ may be the site of a retro-peritoneal hernia. The pericæcal fossæ are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.¹

THE STOMACH.

The **Stomach** is the principal organ of digestion. It is the most dilated part of the alimentary canal, and is situated between the termination of the œsophagus and the commencement of the small intestine. Its form is somewhat pyriform with the large end (*fundus*) directed upward and the small end bent to the right. It is situated in the left hypochondriac and epigastric regions, and is placed, in part, immediately behind the anterior wall of the abdomen and beneath the Diaphragm. Viewing the stomach from in front it appears that the right margin of the œsophagus is continued downward as the upper two-thirds of the lesser curvature of the stomach, the remaining third of this border bending sharply backward and to the right, to complete the smaller curvature (Fig. 491). The greater curvature begins at the left border of the termination of the œsophagus in a somewhat acute angle; it then passes upward and to the left to the under surface of the Diaphragm, with which it lies in contact for some distance, and then sweeps downward with a convexity to the left, and, continued across the middle line of the body, finally turns upward and backward, to terminate at the commencement of the small intestine. It will thus be seen that the stomach may be divided into a main or *cardiac* portion, the long axis of which is directed downward, with a little inclination forward and to the right, and a smaller or *pyloric* portion, the long axis of which is horizontal with an inclination backward. Of the two openings, the *cardiac orifice*, by which it communicates with the œsophagus, is situated slightly to the left of the middle line of the body to the right of the *fundus*, or dilated upper extremity of the stomach, and is directed downward; the other, the *pyloric orifice*, by which it communicates with the small intestine, is on a lower plane, close to the right of the mid-line, and looks directly backward.

FIG. 491.—Diagrammatic outline of the stomach.

The stomach has two surfaces, called anterior and posterior, and two borders, termed the greater and lesser curvatures.

Surfaces.—With regard to the so-called anterior and posterior surfaces of the stomach, it must be borne in mind that these names are not strictly correct, as the anterior surface has a certain amount of inclination upward and the posterior downward.

¹ On the anatomy of these fossæ, see the *Arris and Gale Lectures* by Moynihan, 1899.

The *anterior* surface has a somewhat flattened appearance when the stomach is empty, but when it is full the surface becomes convex. It is in relation with the Diaphragm; the thoracic wall formed by the anterior parts of the seventh, eighth, and ninth ribs of the left side; the left lobe of the liver; and the anterior abdominal wall. Between the part covered by the liver and that covered by the left ribs there is a triangular segment of the anterior wall of the stomach, which is in contact with the abdominal wall and is the only part of the stomach which is visible when the abdominal wall is removed and the viscera allowed to remain *in situ*. It is of about 40 sq. cm. and is of great importance to the surgeon, as the stomach can readily be reached in this situation. Occasionally the transverse colon may be found lying in front of the lower part of the anterior surface of the stomach. The whole of this surface of the stomach is covered by peritoneum.

The *posterior* surface of the stomach is in relation with the Diaphragm, the gastric surface of the spleen, the left supra-renal capsule, the upper part of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the ascending layer of the transverse mesocolon. These structures form a shallow concavity or *bed* on which this surface of the stomach rests. The transverse mesocolon intervenes between the stomach and the duodeno-jejunal junction and commencement of the ileum. Its greater curvature is in relation with the transverse colon and has attached to it the anterior two layers of the great omentum. Almost the whole of this surface is covered with peritoneum, but behind the cardiac orifice there is a small portion of the stomach which is uncovered by peritoneum and is in contact with the Diaphragm and frequently with the upper portion of the left supra-renal capsule.

The *lesser curvature* of the stomach extends between the cardiac and pyloric orifices along the right border of the organ. It descends in front of the left crus of the Diaphragm, along the left side of the eleventh and twelfth dorsal vertebrae, and then turning to the right it crosses the first lumbar vertebra and ascends to the pylorus. It gives attachment to the two layers of the gastro-hepatic omentum, between which blood-vessels and lymphatics pass to reach the organ.

The *greater curvature* is directed to the left, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice, it forms an arch to the left with its convexity upward, the highest point of which is on a level with the costal cartilage of the sixth rib of the left side. It then passes nearly straight downward, with a slight convexity to the left, as low as the costal cartilage of the ninth rib and then turns to the right to end at the pylorus. As it crosses the median line the lowest edge of the greater curvature is about two fingers' breadth above the umbilicus. The lower part of the greater curvature gives attachment to the two anterior layers of the great omentum, between which layers, vessels and lymphatics pass to the organ.

The *cardiac orifice* is the opening by which the œsophagus communicates with the stomach. It is therefore sometimes termed the *œsophageal opening*. It is the most fixed part of the stomach, and is situated about two inches below the highest part of the fundus on a level with the body of the tenth or eleventh dorsal vertebra to the left and a little in front of the aorta. This would correspond on the anterior surface of the body to the articulation of the seventh left costal cartilage to the sternum.

The *pyloric orifice* communicates with the duodenum, the aperture being guarded by a valve. Its position varies with the movements of the stomach. When the stomach is empty the pylorus is situated just to the right of the median line of the body, on a level with the upper border of the first lumbar vertebra. On the anterior surface of the body its position would be indicated by a point one inch below the tip of the ensiform cartilage and a little to the right. As the stomach becomes distended the pylorus moves to the right, and in a fully distended stomach may be situated two or three inches to the right of the median line. Near the pylorus the stomach frequently exhibits a slight dilatation, which is named the *antrum pylorus*.

The size of the stomach varies considerably in different subjects. When moderately distended its greatest length, from the top of the fundus to the lowest part of the greater curvature, is from ten to twelve inches; and its diameter at the widest part from four to five inches. The distance between the two orifices is three to six inches, and the measurement from the anterior to the posterior wall three and a half inches. Its weight, according to Clendinning, is about four ounces and a half, and its capacity in the adult male is five to eight pints.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. When empty, it lies at the back part of the abdomen, some distance from the surface. Its pyloric end is situated close to or very slightly to the right of the middle line, covered in front by the left lobe of the liver, and being on a level with the first lumbar vertebra. When empty, the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end. When the stomach is distended, its surfaces, which are flattened when the organ is empty, become convex. The greater curvature is elevated and carried forward, so that the anterior surface is turned more or less upward and the posterior surface downward, and the stomach brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice: in doing this the

FIG. 492.—The mucous membrane of the stomach and duodenum with the bile-ducts.

Diaphragm is forced upward, contracting the cavity of the chest; hence the dyspnoea complained of, from inspiration being impeded. The apex of the heart is also tilted upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. The left lobe of the liver is pushed to the right side. When the stomach becomes distended the change in the position of the pylorus is very considerable; it is shifted to the right, some two or three inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distention of the stomach the lesser *cul-de-sac* bulges over the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backward. During inspiration the stomach is displaced downward by the descent of the Diaphragm, and elevated by the pressure of the abdominal muscles during expiration. Pressure from without, as from tight lacing, pushes the stomach down toward the pelvis. In disease, also, the position and connection of the organ may be greatly changed, from the accumulation of fluid in the chest or abdomen, or from alteration in size of any of the surrounding

viscera. *Variations according to Age.*—In an early period of development the stomach is vertical, and in the newborn child it is more vertical than later on in life, as owing to the large size of the liver it is more pushed over to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

On looking into the pyloric end of the stomach, the mucous membrane is found projecting inward in the form of a circular fold, the *pyloric valve*, leaving a narrow circular aperture, about half an inch in diameter, by which the stomach communicates with the duodenum.

The *pyloric valve* is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular fibres, which are aggregated into a thick circular ring; the longitudinal fibres and serous membrane being continued over the fold without assisting in its formation.

Structure.—The wall of the stomach consists of four coats: serous, muscular, areolar, and mucous, together with vessels and nerves.

The *serous coat* is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater or lesser curvatures, at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space, along which the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice, there is also a small area uncovered by peritoneum, where the organ is in contact with the under surfaces of the Diaphragm.

The *muscular coat* (Fig. 493) is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of fibres—longitudinal, circular, and oblique.

FIG. 493.—The muscular coat of the stomach.

The *longitudinal fibres* are most superficial; they are continuous with the longitudinal fibres of the œsophagus, radiating in a stellate manner from the cardiac orifice. They are most distinct along the curvatures, especially the lesser, but are very thinly distributed over the surfaces. At the pyloric end they are more thickly distributed, and continuous with the longitudinal fibres of the small intestine.

The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring, which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the *pyloric valve*. They are continuous with the circular fibres of the œsophagus.

The *oblique fibres* are limited chiefly to the cardiac end of the stomach, where they are disposed as a thick uniform layer, covering both surfaces, some passing obliquely from left to right, others from right to left, round the cardiac end.

The *areolar or submucous coat* consists of a loose, filamentous, areolar tissue, connecting the mucous and muscular layers. It supports the blood-vessels previous to their distribution to the mucous membrane: hence it is sometimes called the *vascular coat*.

The *mucous membrane* is thick; its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown color over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature (Fig. 492). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from

FIG. 494.—Pyloric gland.

FIG. 495.—Peptic gastric gland.

being covered with small shallow depressions or alveoli of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric glands*, which are situated perpendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of columnar epithelium; it lines the alveoli, and also for a certain distance the mouths of the gastric glands. This epithelium commences very abruptly at the cardiac orifice, where the cells suddenly change in character from the stratified epithelium of the œsophagus. The cells are elongated, and consist of two parts, the inner or attached portions being granular, and the outer or free parts being clear and occupied by a mucalbuminous substance.

The gastric glands are of two kinds, which differ from each other in structure, and it is believed also in the nature of their secretion. They are named respectively *pyloric* and *cardiac* or *oxyntic glands*. They are both tubular in character, and are formed of a delicate basement-membrane, lined by epithelium. The basement-membrane consists of flattened transparent endothelial cells, with processes which extend between and support the epithelium. The *pyloric glands* (Fig. 494) are most numerous at the pyloric end of the stomach, and from this fact have received their name. They consist of two or three short, closed tubes opening into a common duct, the external orifice of which is situated at the bottom of an alveolus. The cæcal tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with shorter and more cubical cells which are finely granular. The *cardiac glands* (Fig. 495) are found all over the surface of the stomach, but occur most numerous at the cardiac end. Like the pyloric glands, they consist of a duct, into which open two or more cæcal tubes. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the *chief* or the *central* cells of the glands. Between these cells and the basement-membrane are found other darker granular-looking cells, studded throughout the tube at intervals, and giving it a beaded or varicose appearance. These are known as the *parietal* or *oxyntic cells*. Between the glands the mucous membrane consists of a connective-tissue framework with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the *lenticular glands* of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosæ*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner circular, and an outer longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are—the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli. From these latter the *veins* arise, and pursue a straight course downward between the tubules, to the submucous tissue, and terminate either in the splenic and superior mesenteric veins or directly in the portal vein. The *lymphatics* are numerous; they consist of a superficial and deep set, which pass through the lymphatic glands found along the two curvatures of the organ. The *nerves* are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the sympathetic also supply the organ.

Surface Form.—The stomach lies for the most part in the left hypochondriac region, but also slightly in the epigastric region, and is partly in contact with the abdominal wall, partly under cover of the lower ribs on the left side, and partly under the left lobe of the liver. Its cardiac orifice corresponds to the articulation of the seventh left costal cartilage with the sternum. The pyloric orifice is in a vertical line drawn from the right border of the sternum, two and a half or three inches below the level of the sterno-xiphoid articulation. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, as much

sometimes as three inches. The fundus of the stomach reaches, on the left side, as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the ends of the base line.

Surgical Anatomy.—Operations on the stomach are frequently performed. By "gastrotomy" is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterward closed—in contradistinction to "gastrostomy," the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large, by a cut from the ensiform cartilage to the umbilicus, but may be performed by an incision over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned immediately. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures—i. e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition, and in this way the wound is closed. *Gastrostomy* was formerly done in two stages by the *direct* method. The first stage consisted in opening the abdomen, drawing up the stomach into the external wound, and fixing it there; and the second stage, performed from two to four days afterward, consisted in opening the stomach. The operation is now done by a *valvular* method. An incision is commenced opposite the eighth intercostal space, two inches from the median line, and carried downward for three inches. By this incision the fibres of the Rectus muscle are exposed and these are separated from each other in the same line with a steel director. The posterior layer of the sheath, the transversalis fascia and the peritoneum, are then divided, and the peritoneal cavity opened. The anterior wall of the stomach is now seized and drawn out of the wound and a silk suture passed through its muscular and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the rectus are sutured to it. A second incision is made through the skin, over the margin of the costal cartilage, above and a little to the outer side of the first incision. With a pair of dressing forceps a track is made under the skin through the subcutaneous tissue from the one opening to the other and the diverticulum of the stomach is drawn along this track by means of the suture inserted into it; so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex and its margins carefully and accurately sutured to the margin of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of gastric ulcer perforation sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable percentage of cases are cured, provided the operation is undertaken within twelve or fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert's sutures.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favorable, and, in cases of cancer of the pylorus, before operative proceedings are undertaken, the tumor has become so fixed and has so far implicated surrounding parts that removal of the pylorus is impossible and gastro-enterostomy has to be substituted. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible.

Digital dilatation of the pylorus for simple stricture was first performed by Loreta. He exposed the stomach and opened it by a transverse incision near the pylorus. He then inserted the forefingers of both hands and passed these through the pylorus and stretched it with some degree of force. The operation has now, however, dropped out of use and been replaced by pyloro-plasty. This consists in making a longitudinal incision from the stomach through the pylorus into the duodenum, and converting this longitudinal incision into a transverse one by traction at the centre of the incision, and retaining it permanently in this position by sutures.

THE SMALL INTESTINE.

The small intestine is a convoluted tube, extending from the pylorus to the ileo-cæcal valve, where it terminates in the large intestine. It is about twenty feet in length,¹ and gradually diminishes in size from its commencement to its

¹ Treves states that, in one hundred cases, the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches: but that it varies very much, the extremes in the male being 31 feet 10 inches in one case, and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

termination. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum; it is in relation, in front, with the great omentum and abdominal parietes; and connected to the spine by a fold of peritoneum, the mesentery. The small intestine is divisible into three portions—the duodenum, the jejunum, and ileum.

The **duodenum** has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine. Its course presents a remarkable curve, which in the adult, as regards the greater part of its extent, is U-shaped; though sometimes, in consequence of the transverse portion being very short or altogether wanting, it partakes more of the character of the letter V. In children, up to the age of about seven, the duodenum is annular; its two extremities are on about the same level; and between them it describes a regular curve embracing the head of the pancreas, the neck of which lies between the two extremities of the ring.

In the adult the course of the duodenum is as follows: commencing at the pylorus the direction of the first portion depends upon the amount of distention of the stomach and therefore upon the position of the pylorus. When the stomach is empty and the pylorus situated at the right of the upper border of the first lumbar vertebra, it is nearly horizontal and transverse; but where the stomach is distended, in consequence of the alteration of the position of the pylorus to the right the proximal end of the duodenum also becomes altered in position, while the distal end remains fixed and the direction of this portion of the bowel is now antero-posterior. Whether directed transversely or antero-posteriorly, it reaches the under surface of the liver, where it takes a sharp curve and descends along the right side of the vertebral column, for a variable distance, generally to the body of the fourth lumbar vertebra. It now takes a second bend, and passes across the front of the vertebral column from right to left and finally ascends on the left side of the vertebral column and aorta to the level of the upper border of the second lumbar vertebra and there terminates in the jejunum. As it unites with the jejunum it often turns abruptly forward, forming the *duodeno-jejunal angle*. From the above description it will be seen that the duodenum may be divided for purposes of description into four portions—superior, descending, transverse, and ascending.

The first or *superior portion* (Fig. 496) is very variable in length, but is usually estimated as being about two inches. Beginning at the pylorus, it ends at the neck of the gall-bladder. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum, but a small part of its posterior surface near the neck of the gall-bladder and the inferior vena cava is uncovered. It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation above and in front with the quadrate lobe of the liver and the gall-bladder; behind with the gastro-duodenal artery, the common bile-duct, and the vena porta; and below with the head of the pancreas.

The second or *descending portion* is between three and four inches in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue (Fig. 490). The portions of the descending part of the duodenum above and below this interspace are named the supra- and infra-colic portions, and are covered in front by peritoneum. The right side of the supra-colic portion is covered by peritoneum derived from the anterior surface of the right kidney, the left side of the same portion being covered by the peritoneum forming the lesser sac. The infra-colic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is uncovered by peritoneum. It is in relation, in front, with the transverse colon, and above this with the liver; behind with the front of the right kidney, to which

it is connected by loose areolar tissue, the renal vessels and the vena cava inferior; at its inner side is the head of the pancreas, and the ductus communis choledochus; to its outer side is the hepatic flexure of the colon. The common bile-duct and the

FIG. 496.—Relations of duodenum, pancreas and spleen. (From a cast by Professor Birmingham.¹) The dotted line represents the line of attachment of the transverse mesocolon.

pancreatic duct perforate the inner side of this portion of the intestine obliquely, some three or four inches below the pylorus. The relations of the second part of the duodenum to the right kidney present considerable variations.

¹ In the subject from which the cast was taken the left kidney was lower than normal.

The third or *transverse portion* (pre-aortic portion) varies much in length; when the duodenum assumes the ordinary U-shaped form, it measures from two to three inches; but when it presents the rarer V-shaped form, it is practically wanting or very much reduced in length. It commences at the right side of the fourth lumbar vertebra and passes from right to left, with a slight inclination upward, in front of the great vessels and crura of the Diaphragm, and ends in the fourth portion just to the left of the abdominal aorta. It is crossed by the superior mesenteric vessels and mesentery. Its front surface is covered by the anterior layer of the mesentery, but near the middle line it is separated from this layer of the mesentery by the superior mesenteric vessels as they cross this portion of the duodenum. Its posterior surface is uncovered by peritoneum, except toward its left extremity, where the posterior layer of the mesentery may sometimes be found covering it to a variable extent. This surface rests upon the aorta, the vena cava inferior, and the crura of the Diaphragm. By its upper surface this portion of the duodenum is in relation with the head of the pancreas.

The fourth or *ascending portion* of the duodenum is about two inches long. It ascends on the left side of the vertebral column and aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forward to become the jejunum, forming the *duodeno-jejunal flexure*. It is covered entirely in front and partly at the sides by peritoneum, derived from the left portion of the mesentery. It touches the left kidney, slightly overlapping its inner margin, and rests upon the left crus of the Diaphragm.

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodeno-jejunal flexure is further bound down and fixed by a structure to which the name of *musculus suspensorius duodeni* has been given. This structure commences in the connective tissue around the coeliac axis and left crus of the Diaphragm, and passes downward to be inserted into the superior border of the duodeno-jejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, plain muscular fibres mixed with the fibrous tissue, of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

Vessels and Nerves.—The *arteries* supplying the duodenum are the pyloric and pancreatico-duodenal branches of the hepatic, and the inferior pancreatico-duodenal branch of the superior mesenteric. The *veins* terminate in the splenic and superior mesenteric. The *nerves* are derived from the solar plexus.

Jejunum and Ileum.—The remainder of the small intestine from the termination of the duodenum is named *jejunum* and *ileum*; the former term being given to the upper two-fifths and the latter to the remaining three-fifths. There is no morphological line of distinction between the two, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows:

The *jejunum*, which derives its name from the Latin word *jejunus* (empty), because it was formerly supposed to be empty after death, is wider, its diameter being about one inch and a half, and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. Its valvulae conniventes are large and thickly set and its villi are larger than in the ileum. The glands of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. Brunner's glands are only found in the upper part of the jejunum. By grasping the jejunum between the finger and thumb the valvulae conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The *ileum*, so called from the Greek word *εἰλεῖν* (to twist), on account of its numerous coils and convolutions, is narrow, its diameter being one inch and a quarter, and its coats thinner and less vascular than those of the jejunum. It possesses but few valvulae conniventes, and they are small and disappear entirely toward its lower end, but Peyer's patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the *mesentery*, which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border, about six inches in length, is attached to the abdominal wall from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 490). Its length is about eight inches from its commencement to its termination at the intestine, and it is rather longer about its centre than at either end of the bowel. According to Lockwood, it tends to increase in length as age advances. Between the two layers of which it is composed are contained blood-vessels, nerves, lacteals, and lymphatic glands, together with a variable amount of fat.

Meckel's Diverticulum.—Occasionally there may be found connected with the lower part of the ileum, on an average of about three and a half feet from its termination, a blind diverticulum or tube, varying in length. It is attached to and communicates with the lumen of the bowel by one extremity, and by the other is unattached or may be connected with the abdominal wall or some other portion of the intestine by a fibrous band. This is Meckel's diverticulum, and represents the remains of the vitelline or omphalo-mesenteric duct, the duct of communication between the umbilical vesicle and the alimentary canal in early foetal life.

Structure.—The wall of the small intestine is composed of four coats—serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum. The first or ascending portion of the duodenum is almost completely surrounded by this membrane near its pyloric end, but only in front at the other extremity; the second or descending portion is covered by it in front, except where it is carried off by the transverse colon; and the third or transverse portion lies behind the peritoneum, which passes over it, without being closely incorporated with the other coats of this part of the intestine, and is separated from it in the middle line by the superior mesenteric artery. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The *muscular coat* consists of two layers of fibres, an external or longitudinal, and an internal or circular layer. The *longitudinal fibres* are thinly scattered over the surface of the intestine, and are more distinct along its free border. The *circular fibres* form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of plain muscle-cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The *areolar or submucous coat* connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a nidus for the subdivision of the nutrient vessels, previous to their distribution to the mucous surface.

The *mucous membrane* is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscular fibres, the *muscularis mucosae*; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in which the blood-vessels and nerves ramify. Lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestines are columnar in character. They

are granular in appearance, and possess a clear, oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, marked by vertical striæ, which were formerly believed to be minute channels by which the chyle was taken up into the interior of the cell, and by them transferred to the lacteal vessels of the mucous membrane.

The mucous membrane presents for examination the following structures contained within it or belonging to it:

Valvulæ conniventes.

Villi.

Simple follicles.

Glands { Duodenal glands.
Solitary glands.
Peyer's or agminate glands.

The *valvulæ conniventes* (valves of Kerkring) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together by submucous tissue; they contain no muscular fibres, and, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine

FIG. 497.—Diagrammatic section of a villus. (Watney.) *ep*. Epithelium only partially shaded in. *l*. Central chyle-vessel; the cells forming the vessel have been less shaded to distinguish them from the cells of the parenchyma of the villus. *m*. Muscle-fibres running up by the side of the chyle-vessel. It will be noticed that each muscle-fibre is surrounded by the reticulum, and by this reticulum the muscles are attached to the cells forming the membrana propria, as at *e'*, or to the reticulum of the villus. *lc*. Lymph-corpuscles, marked by a spherical nucleus and a clear zone of protoplasm. *l'*. Upper limit of the chyle-vessel. *e, e, e'*. Cells forming the membrana propria. It will be seen that there is hardly any difference between the cells of the parenchyma, the endothelium of the upper part of the chyle-vessel, and the cells of the membrana propria. *v*. Blood-vessels. *z*. Dark line at base of the epithelium formed by the reticulum. It will be seen that the reticulum penetrates between all the other elements of the villus. The reticulum contains thickenings or "nodal points." The diagram shows that the cells of the upper part of the villus are larger and contain a larger zone of protoplasm than those of the lower part. The cells of the upper part of the chyle-vessel differ somewhat from those of the lower part in that they more nearly resemble the cells of the parenchyma.

for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once round the bowel, but occasionally two or three times. The spiral arrangement is the characteristic one of the shark family of fishes. The larger folds are about one-third of an inch in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but

begin to appear about one or two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulæ conniventes retard the passage of the food along the intestines, and afford a more extensive surface for absorption.

The villi are minute, highly vascular processes, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. In shape, according to Rauber, they are short and leaf-shaped in the duodenum, tongue-shaped in the jejunum, and filiform in the ileum. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Krause estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

Structure of the Villi (Fig. 497).—The structure of the villi has been studied by many eminent anatomists. We shall here follow the description of Watney,¹ whose researches have a most important bearing on the physiology of that which is the peculiar function of this part of the intestine, the absorption of fat.

FIG. 498.—Villi of small intestine. (Cadiat.)

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the epithelium, the basement membrane and muscular tissue of the mucosa, these structures being supported and held together by retiform lymphoid tissue.

These structures are arranged in the following manner: situated in the centre of the villus is the lacteal, terminating near the summit in a blind extremity; running along this vessel are unstriated muscular fibres; surrounding it is a plexus of capillary vessels, the whole being enclosed by a basement-membrane, and covered by columnar epithelium. Those structures which are contained within the basement-membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—

¹ *Phil. Trans.*, vol. clxv., pt. ii.

are surrounded and enclosed by a delicate reticulum which forms the matrix of the villus, and in the meshes of which are found large flattened cells with an oval nucleus, and, in smaller numbers, lymph-corpuscles. These latter are to be distinguished from the larger cells of the villus by their behavior with reagents, by their size, and by the shape of their nucleus, which is spherical. Transitional forms, however, of all kinds are met with between the lymph-corpuscles and the proper cells of the villus. Nerve-fibres are contained within the villi; they form ramifications throughout the reticulum.

The *lacteals* are in some cases double, and in some animals multiple. Situated in the axis of the villi, they commence by dilated cæcal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

The *muscular fibres* are derived from the muscularis mucosæ, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement membrane.

The *blood-vessels* form a plexus between the lacteal and the basement membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that the chyle passes in the process of absorption by the villi. That is to say, it passes first of all into the columnar epithelial cells, and, escaping from them, is carried into the reticulum of the villus, and thence into the central lacteal.

The *simple follicles*, or *crypts of Lieberkühn* (Figs. 499, 500), are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots scattered between the villi. Their walls are thin, consisting of a basement-membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The *duodenal* or *Brunner's glands* are limited to the duodenum and commencement of the jejunum. They are small, flattened, granular bodies embedded in the submucous areolar tissue, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They are small compound acino-tubular glands, and much resemble the small glands which are found in the mucous membrane of the

FIG. 499.—Longitudinal section of crypts of Lieberkühn. Goblet-cells seen among the columnar epithelial cells. (Klein and Noble Smith.)

FIG. 500.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)

mouth. They are believed by Watney to be direct continuations of the pyloric glands of the stomach. They consist of a number of tubular alveoli, lined by epithelium, and opening by a single duct on the inner surface of the intestine.

The **solitary glands** (*glandule solitariae*) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. They are small, round, whitish bodies, from half a line to a line in diameter. Their free surface is covered with villi, and each gland is surrounded by the openings of the follicles of Lieberkühn. They are now recognized as lymph-follicles, and consist of a dense interlacing retiform tissue closely packed with lymph-corpuscles, and permeated with an abundant capillary network (Fig. 501). The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, whence they form slight projections of its epithelial layer, after having penetrated the muscularis mucosæ. The villi which are situated on them are generally absent from the very summit (or "cupola," as Frey calls it) of the gland.

Peyer's glands (agminated glands) (Figs. 501 to 504) may be regarded as aggregations of solitary glands, forming circular or oval patches from twenty to thirty in number, and varying in length from half an inch to four inches. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most

FIG. 501.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.

FIG. 502.—Patch of Peyer's glands. From the lower part of the ileum.

FIG. 503.—A portion of the above magnified.

distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary glands covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as

a rule, possess villi on their free surface. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life.

FIG. 504.—Vertical section of one of Peyer's patches from man, injected through its lymphatic canals. *a*, Villi with their chyle-passages. *b*, Follicles of Lieberkühn. *c*, Muscularis mucosæ. *d*, Cupola or apex of solitary glands. *e*, Mesial zone of glands. *f*, Base of glands. *g*, Points of exit of the chyle-passages from the villi, and entrance into the true mucous membrane. *h*, Retiform arrangement of the lymphatics in the mesial zone. *i*, Course of the latter at the base of the glands. *k*, Confluence of the lymphatics opening into the vessels of the submucous tissue. *l*, Follicular tissue of the latter.

They are largely supplied with blood-vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are found throughout

FIG. 505.—Meissner's plexus. (Klein and Noble Smith.)

the small intestine are especially abundant around these patches; here they form rich plexuses with sinuses around the glands (Fig. 504).

Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent anastomoses to the free border, where they also anastomose with other branches running round the opposite surface of the gut. From these vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The veins have a similar course and arrangement to the arteries. The *lymphatics of the small intestines* (lacteals) are arranged in two sets, those of the mucous membrane, and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above, and form an intricate plexus in the mucous and submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary glands, and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a close plexus, and throughout their course communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement of the lacteal vessels at the attached border of the gut.

The *nerves of the small intestines* are derived from the plexuses of sympathetic nerves around the superior mesenteric artery. From this source they run to a plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (*Auerbach's plexus*), from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (*Meissner's plexus*), and is formed by branches which have perforated the circular muscular fibres (Fig. 505). This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosæ and to the villi and mucous membrane.

THE LARGE INTESTINE.

The large intestine extends from the termination of the ileum to the anus. It is about five feet in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anus. It differs from the small intestine in its greater size, its more fixed position, its sacculated form, and in possessing certain appendages to its external coat, the *appendices epiploicæ*. Further, its longitudinal muscular fibres do not form a continuous layer around the gut, but are arranged in three longitudinal bands or *teniæ*. The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. It commences in the right inguinal region, in a dilated part, the *cæcum*. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; it here takes a bend (the *hepatic flexure*) to the left, and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again (the *splenic flexure*), and descends through the left lumbar region to the left iliac fossa, where it becomes con-

FIG. 506.—The cæcum and colon laid open to show the ileo-cæcal valve.

volted, and forms the sigmoid flexure; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the cæcum, colon, and rectum.

The **Cæcum** (*cæcus, blind*) is the large blind pouch, or *cul-de-sac*, situated below the ileo-cæcal valve, in which the large intestine commences (Fig. 506). Its blind end is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name *caput cæcum coli* was applied to it. Its size is variously estimated by different authors, but on an average it may be said to be two and a half inches in length and three in breadth. It is situated in the right iliac fossa, above the outer half of Poupart's ligament: it rests on the Ilio-psoas muscle and lies immediately behind the abdominal wall. As a rule, it is entirely enveloped on all sides by peritoneum, but in a certain number of cases (6 per cent., Berry) the peritoneal covering is not complete, so that a small portion of the upper end of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. The cæcum lies quite free in the abdominal cavity and enjoys a considerable amount of movement, so that it often becomes herniated down the right inguinal canal, and has occasionally been found in an inguinal hernia on the left side. The cæcum varies in shape, but, according to Treves, in man it may be classified under one of four types. In early foetal life it is short, conical, and broad at the base, with its apex turned upward and inward toward the ileo-cæcal junction. It then resembles the cæcum of some of the monkey tribe, *e. g.*, Mangabey monkey. As the foetus grows the cæcum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inward of the apex toward the ileo-cæcal junction. This form is seen in others of the monkey tribe, *e. g.*, the spider monkey. As development goes on, the lower part of tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the vermiform appendix, hanging from a conical projection, the cæcum. This is the infantile form, and as it may persist throughout life, in about 2 per cent. of cases, it is regarded by Treves as the *first* of his four types of human cæca. The cæcum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the *second* type, the conical cæcum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules are of equal size, and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The *third* type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right saccule, and the original apex, with the appendix attached, is pushed over to the left toward the ileo-cæcal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and postero-external bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The *fourth* type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has been atrophied, so that the original apex of the cæcum, with the appendix, is close to the ileo-cæcal junction, and the anterior band courses inward to the same situation. This type is present in about 4 per cent. of cases.

The **vermiform appendix** is a long, narrow, worm-shaped tube, which starts from what was originally the apex of the cæcum, and may pass in several directions: upward behind the cæcum; to the left behind the ileum and mesentery; or downward and inward into the true pelvis. It varies from one to nine inches in length, its average being about three inches. It is retained in position by a fold of peritoneum derived from the left leaf of the mesentery, which forms a mesentery for it. This is triangular in shape, but does not extend the whole length of the

tube, but leaves the distal third free and completely covered by peritoneum. Between its two layers lies a considerable branch of the ileo-colic artery, the artery of the appendix. Its canal is small, extends throughout the whole length of the tube, and communicates with the cæcum by an orifice which is placed below and behind the ileo-cæcal opening. It is sometimes guarded, according to Gerlach, by a semilunar valve formed by a fold of mucous membrane, but this is by no means constant. Its coats are the same as those of the intestine: serous, muscular, submucous, and mucous, the latter containing an abundant supply of retiform tissue, especially in young subjects.

It is stated that the vermiform appendix tends to undergo obliteration as an involution change of a functionless organ.

The Ileo-cæcal Valve (*Valvula Bauhini*).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the cæcum with the colon. The opening is guarded by a valve, consisting of two semilunar segments, an upper or colic and lower or cæcal, which project into the lumen of the large intestine. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, which is more concave and longer, is attached to the point of junction of the ileum with the cæcum. At each end of the aperture the two segments of the valve coalesce, and are continued as a narrow membranous ridge around the canal for a short distance, forming the *fræna* or *retinacula* of the valve. The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed.

Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across from one portion of the intestine to the other. When these are divided or removed, the ileum may be drawn outward, and all traces of the valve will be lost, the ileum appearing to open into the large intestine by a funnel-shaped orifice of large size.

The surface of each segment of the valve directed toward the ileum is covered with villi, and presents the characteristic structure of the mucous membrane of the small intestine; while that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margin of the valve.

When the cæcum is distended, the margins of the opening are approximated so as to prevent any reflux into the ileum.

The **colon** is divided into four parts—the ascending, transverse, descending, and the sigmoid flexure.

The **ascending colon** is smaller than the cæcum, with which it is continuous. It passes upward, from its commencement at the cæcum, opposite the ileo-cæcal valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression, the *impressio colica*; here it bends abruptly inward to the left, forming the *hepatic flexure*. It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the *Quadratus lumborum* and *Transversalis* muscles, and with the front of the lower and outer part of the right kidney (Figs. 507 and 508). Sometimes the peritoneum almost completely invests it, and forms a distinct but narrow mesocolon.¹ It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

¹ Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a mesocolon may be expected on the left side in 36 per cent. of all cases, and on the right in 26 per cent. (*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.)

The transverse colon, the longest part of the large intestine, passes transversely from right to left across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward

FIG. 507.—Diagram of the relations of the large intestine and kidney, from behind.

beneath the lower end of the spleen, forming the *splenic flexure*. In its course it describes an arch, the concavity of which is directed backward toward the vertebral column and a little upward; hence the name *transverse arch of the colon*. This is the most movable part of the colon, being almost completely invested by

peritoneum, and connected to the spine behind by a large and wide duplicature of that membrane, the *transverse mesocolon*. It is in relation, by its upper surface, with the liver and gall-bladder, the great curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the great omentum and the abdominal parietes; its posterior surface on the right side is in relation with the second portion of the duodenum, and on the left is in contact with some of the convolutions of the jejunum and ileum.

The **descending colon** passes downward through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns inward toward the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the sigmoid flexure. At its commencement it is connected with the Diaphragm by a fold of peritoneum, the *phreno-colic* ligament (see page 902). It is retained in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and the Quadratus lumborum and Transversalis muscles (Figs. 507, 508). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **sigmoid flexure** is the narrowest part of the colon: it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the margin of the crest of the ilium, and ending in the rectum at the brim of the true pelvis opposite the left sacro-iliac symphysis. It curves in the first place forward, downward, and inward for about two inches, and then forms a loop, which varies in length and position, and which terminates in the rectum.¹ The first portion is in close relation with the iliac fascia, and is covered by peritoneum on its sides and anterior surface only. The loop is entirely surrounded by peritoneum, and is retained in its place by a loose fold of peritoneum, the *sigmoid mesocolon*, which connects it to the Psoas muscle. This loop, which normally hangs downward, sometimes into the true pelvis, is very movable, and may be displaced upward in cases of distention of the pelvic viscera. The sigmoid flexure is in relation in front with the small intestines and abdominal parietes. The sigmoid mesocolon is attached to a line running downward and inward from the crest of the ilium, across the Psoas muscle, to become continuous with the *mesorectum* near the bifurcation of the common iliac artery (Fig. 490). In its left layer is the inter-sigmoid fossa (see page 905).

The **rectum** is the terminal part of the large intestine, and extends from the sigmoid flexure to the anal orifice. The superior limit cannot be determined precisely, since there is no point of demarcation between the sigmoid flexure and the first part of the rectum; but the brim of the true pelvis, opposite the left sacro-iliac joint, is arbitrarily given as its point of commencement. From this point it passes downward, backward, and to the right to the level of the third sacral vertebra, where it lies in the middle line. This is the *first part* of the rectum. The *second part* curves forward and is continued downward as far as the apex of the prostate gland, about an inch in front of the tip of the coccyx. From this point the bowel is directed backward, and, passing downward, terminates at the anal orifice. This is the third portion of the rectum, or, as described by Symington, the *anal canal*. It will be seen, therefore, that the rectum presents two antero-posterior curves: the first, with its convexity backward, is due to the conformation of the sacro-coccygeal column, and represents the arc of a circle, the centre of which is opposite the third sacral vertebra. The lower one has its convexity forward, and is angular. Its centre corresponds to a line drawn between the anterior parts of the ischial tuberosities. Two lateral curves are also described:

¹ Treves describes the sigmoid flexure somewhat differently. He includes in his description of this portion of the bowel the upper part of the rectum, and makes it terminate opposite the third portion of the sacrum. Instead of forming a sigmoid curve, he describes it as a large loop or bend, more like the Greek letter Ω (omega).

the one to the right, opposite the junction of the third and fourth sacral vertebræ; the other to the left, opposite the sacro-coccygeal articulation. They are of little importance.

FIG. 508.—The relations of the viscera and large vessels of the abdomen. (Seen from behind, the last dorsal vertebra being well raised.)

The length of the rectum is about eight inches. The first part is four inches, the second three, and the third one to one and a half, being rather longer in the male than in the female. The rectum is narrower in its upper part than the sig-

moid flexure, but is capable of considerable distention. In the lower part of the second portion it becomes a transverse slit, its anterior and posterior walls lying close together when the tube is empty, on account of the organs in the front part of the pelvis pushing the rectum backward on the sacrum and coccyx. The third part of the rectum, the anal canal, is also a slit, with, however, an antero-posterior direction, so that its lateral walls are in apposition (Fig. 509).

The first portion of the rectum is almost completely surrounded by peritoneum, and is connected to the anterior surface of the sacrum by a double fold, called the *mesorectum*, which is continuous above with the sigmoid mesocolon. The mesorectum is triangular in shape, the apex of which ends below at the third sacral vertebra; between its two layers is the superior hemorrhoidal artery. The second portion has no mesorectum, but is covered in front and laterally by peritoneum at its upper part; gradually the peritoneum leaves its sides, and about an inch above the prostate is reflected from the anterior surface of the bowel on to the posterior wall of the bladder in the male, and the upper fifth of the posterior wall of the vagina in the female, forming the recto-vesical and recto-vaginal pouches, respectively. The third portion of the rectum has no peritoneal covering. The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the recto-vesical pouch is about three inches; that is to say, the height to which an ordinary index finger can reach from the anus. In the female the height of the recto-vaginal pouch is about $2\frac{1}{2}$ inches from the anal orifice.

The *first portion* of the rectum is in relation, behind, with the mesorectum and the superior hemorrhoidal artery, the left Pyriformis muscle, and left sacral plexus of nerves, which separate it from the anterior surface of the upper sacral vertebra; to its left side are the branches of the left internal iliac artery and the left ureter; in front it is separated, in the male, from the posterior surface of the bladder; in the female, from the posterior surface of the uterus and its appendages, by some convolutions of the small intestine, and frequently by the sigmoid flexure of the colon. The *second portion* of the rectum is in relation, in front, in the male, with the recto-vesical pouch, the triangular portion of the base of the bladder, the vesiculæ seminales, and vasa deferentia, and more anteriorly with the under surface of the prostate. In the female, with the posterior wall of the vagina below, and the recto-vaginal pouch above, in which are some convolutions of the small intestine. The *third portion* or *anal canal* is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter; in the empty condition it presents the appearance of a longitudinal slit. In the male it is separated from the membranous portion and bulb of the urethra by a triangular space; and in the female it is separated from the lower end of the vagina by the perineal body. Laterally is the fat in the ischio-rectal fossæ.

Structure.—The large intestine has four coats—serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cæcum is completely covered by the serous membrane, except in a small percentage of cases (5 or 6 per cent.), where a small portion of the upper end of the posterior surface is uncovered. The ascending and descending colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered.¹ The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The sigmoid flexure is completely surrounded, except along the line to which the sigmoid mesocolon is attached. The upper part of the rectum is completely invested by the peritoneum, except along the attachment of the mesorectum; the middle portion is covered only on its anterior surface, and part of its sides in the upper portion; and the lower portion is entirely devoid of any serous covering. In the course of the colon and upper part of the rectum the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicæ*. They are chiefly appended to the transverse colon.

The *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres.

The *longitudinal fibres*, although found to a certain extent all round the intestine, do not form a uniform layer over the whole surface of the large intestine. In the cæcum and colon they are especially collected into three flat longitudinal bands or *tæniæ*, each being about half an inch in width. These bands commence at the attachment of the vermiform appendix, which is surrounded by a uniform layer of longitudinal muscular fibres, to the cæcum: one, the posterior, is placed along the attached border of the intestine; the anterior, the largest, corresponds along the arch of the colon to the attachment of the great omentum, but is in front in the ascending and descending colon and sigmoid flexure; the third, or lateral band, is found on the inner side of the ascending and descending colon, and on the under aspect of the transverse colon. These bands are nearly one-half shorter than the other coats of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the sigmoid flexure the longitudinal fibres become more scattered; but upon its lower part, and round the rectum, they spread out and form a layer which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where it forms two bands, than on the lateral surfaces. In addition to the muscular fibres of the bowels, two bands of plain muscular tissue arise from the second and third coccygeal vertebræ, and pass downward and forward to blend with the longitudinal muscular fibres on the posterior wall of the anal canal. These are known as the *recto-coccygeal* muscles.

The *circular fibres* form a thin layer over the cæcum and colon, being especially accumulated in the intervals between the sacculi; in the rectum they form a thick layer, especially at its lower end, where they become numerous, and constitute the Internal sphincter.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane*, in the cæcum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the œsophagus. When the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, some of which, near the anus, are longitudinal in direction, and are effaced by the distention of the gut. Besides these there are certain permanent folds, of a semilunar shape, known as Houston's valves.² They are usually three in number; sometimes a fourth is found, and occasionally only two are present. One is situated

¹ See foot-note, p. 924.

² *Dublin Hosp. Reports*, vol. v. p. 163.

near the commencement of the rectum, on the right side; another extends inward from the left side of the tube, opposite the middle of the sacrum; the largest and most constant one projects backward from the fore part of the rectum, opposite the base of the bladder. When a fourth is present, it is situated about an inch above the anus on the back of the rectum. These folds are about half an inch in width, and contain some of the circular fibres of the gut. In the empty state of the intestine they overlap each other, as Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along the canal of the intestine. Their use seems to be "to support the weight of fecal matter, and prevent its urging toward the anus, where its presence always excites a sensation demanding its discharge."

As in the small intestine, the mucous membrane consists of a muscular layer, the *muscularis mucosæ*; of a quantity of retiform tissue in which the vessels ramify; of a basement-membrane and epithelium, which is of the columnar variety, and exactly resembles the epithelium found in the small intestine. The mucous membrane of this portion of the bowel presents for examination simple follicles and solitary glands.

The *simple follicles* are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The *solitary glands* (Fig. 510) in the large intestine are most abundant in the *cæcum* and *vermiform appendix*, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Solitary gland
FIG. 510.—Minute structure of large intestine.

Vessels and Nerves.—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The rectum is supplied mainly by the superior hemorrhoidal branch of the inferior mesenteric, but also at its lower end by the middle hemorrhoidal from the internal iliac, and the inferior hemorrhoidal from the pudic artery. The superior hemorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other as far as the Internal sphincter, where they anastomose with the other hemorrhoidal arteries and form a series of loops around the anus. The veins of

the rectum commence in a plexus of vessels which surrounds the lower extremity of the intestinal canal. In the vessels forming this plexus are small saccular dilations just within the margin of the anus; from it about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about five inches, running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hemorrhoidal vein. This arrangement is termed the *hemorrhoidal plexus*; it communicates with the tributaries of the middle and inferior hemorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The nerves are derived from the plexuses of the sympathetic nerve around the branches of the superior and inferior mesenteric arteries that are distributed to the large intestine. They are distributed in a similar way to those in the small intestine. The lymphatic vessels of the large intestine are found in the submucosa, where they form a wide-meshed network, and also, more deeply seated, beneath the simple follicles. Those from the colon open into the mesenteric glands; those from the sigmoid flexure into the lumbar glands; those from the rectum enter the glands which are situated in the hollow of the sacrum; and those around the anus open into the glands in the groin.

Surface Form.—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—*i. e.* the left lumbar and inguinal regions and the left half of the umbilical region—whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also the hypogastric. The cæcum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal region, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct tumor. The position of the base of the vermiform appendix is indicated by a point two inches from the anterior superior spinous process of the ilium, in a line drawn from this process to the umbilicus. This is known as *McBurney's spot*. Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior spines of the ilia and marking the point where this line intersects the right semilunar line.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculæ seminales can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossæ can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch up the bowel. By gradual dilatation of the sphincter, the whole hand can be introduced into the rectum so as to reach the descending colon. This method of exploration is rarely, however, required for diagnostic purposes.

Surgical Anatomy.—The small intestines are much exposed to injury, but, in consequence of their elasticity and the ease with which one fold glides over another, they are not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, three lines in length, no extravasation of the contents of the bowel takes place. The mucous membrane becomes everted and plugs the little opening. The bowels, therefore, may be safely punctured with a fine capillary trocar, in cases of excessive distension of the intestine with gas, without fear of extravasation. A longitudinal wound gapes more than a transverse, owing to

the greater amount of circular muscular fibres. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicæ, or an adherent vermiform appendix or Fallopian tube. Intussusception or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileo-cæcal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may lead to intestinal obstruction.

Resection of a portion of the intestine may be required in cases of gangrenous gut; in cases of intussusception; for the removal of new growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the gut must be clamped on either side of this portion in order to prevent the escape of any of the contents of the bowel during the operation. The portion of bowel is then separated above and below by means of scissors. If the portion removed is small, it may be simply removed from the mesentery at its attachment and the bleeding vessels tied; but if it is large, it will be necessary to remove also a triangular piece of the mesentery, and, having secured the vessels, suture the cut edges of this structure together. The surgeon then proceeds to unite the cut ends of the bowel together by the operation of what is termed end-to-end anastomosis. There are many ways of doing this, which may be divided into two classes: one where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbins; and the other, where the operation is performed by suturing the ends of the bowel in such a manner that the peritoneum covering the free divided ends of the bowel is brought into contact, so that speedy union may ensue.

The vermiform appendix is very liable to become inflamed. This condition may be set up by the appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distention of the cæcum. As the result of this its blood-supply, which is mainly through one large artery running in the mesentery, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of feces or a foreign body in it. The inflammation may result in ulceration and perforation, or, if the torsion is very acute, in gangrene of the appendix. These conditions may require operative interference, and in cases of recurrent attacks of appendicitis it is generally advisable to remove this diverticulum of the bowel. In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved, it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. Occasionally ulceration of the duodenal glands may occur in cases of burns, but is not a very common complication. The ulcer may perforate one of the large duodenal vessels, and may cause death from hemorrhage, or it may perforate the coats of the intestine and produce fatal septic peritonitis. The diameter of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distention is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to give way from the distention, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the meso-sigmoid flexure is elongated. The gut at this part being loaded with feces, from its weight falls over the gut below, and so gives rise to the twist.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no inflection of the epiblast, and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the inflection of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favors prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the

muçous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about five inches in the submuçous tissue, pierce the muscular coats, and are liable to become constricted at this by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing and causes it to become a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three inches from the anus, so that it is not desirable to remove more than two and a half inches of the entire circumference of the bowel, for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is necessary to remove a less length of the tube in this sex. Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with antiseptic wool until the operation is completed and then the edges of the wound in the peritoneum accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin, and the greater and lesser sacro-sciatic ligaments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downward and inward through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outward, the whole of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portion of the gut, if healthy. The two divided ends of the gut can then be approximated and sutured together in front, the posterior part being left open for drainage.

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum, as soon as the disease is recognized, in the hope that the rate of growth may be retarded by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of colotomy may be performed either in the inguinal or lumbar region; but inguinal colotomy has in the present day almost superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process of the meso-colon can be formed which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being almost entirely surrounded by peritoneum, a coil can be drawn out of the wound and the greater part of its calibre removed, leaving the remainder attached to the meso-colon, which forms a spur, much the same as in an artificial anus caused by sloughing of the gut after a strangulated hernia, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewn to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by passing a needle threaded with carbolized silk through the meso-colon close to the gut and then through the abdominal wall. The intestine is now sewn to the skin all round, the suture passing only through the serous and muscular coats. The wound is dressed, and on the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened and removed with scissors.

Lumbar colotomy is performed by placing the patient on the side opposite to the one to be operated on, with a firm pillow under the loin. A line is then drawn from the anterior superior to the posterior superior spine of the ilium, and the mid-point of this line (Heath) or half an inch behind the mid-point (Allingham) is taken, and a line drawn vertically upward from it to the last rib. This line represents, with sufficient correctness, the position of the normal colon. An oblique incision four inches in length is now made midway between the last rib and the crest of the ilium, so that its centre bisects the vertical line, and the following parts successively divided: (1) The skin, superficial fascia, with cutaneous vessels and nerves and deep fascia. (2) The posterior fibres of the External oblique and anterior fibres of the Latissimus dorsi.

(3) The Internal oblique. (4) The lumbar fascia and the external border of the Quadratus lumborum. The edges of the wound are now to be held apart with retractors, and the transversalis fascia will be exposed. This is to be opened with care, commencing at the posterior angle of the incision. If the bowel is distended, it will bulge into the wound, and no difficulty will be found in dealing with it. If, however, the gut is empty, this bulging will not take place, and the colon will have to be sought for. The guides to it are the lower end of the kidney, which will be plainly felt, and the outer edge of the Quadratus lumborum. The bowel having been found, is to be drawn well up into the wound, and it may be opened at once and the margins of the openings stitched to the skin at the edge of the wound; or, if the case is not an urgent one, it may be retained in this position by two harelip pins passed through the muscular coat, the rest of the wound closed, and the bowel opened in three or four days, when adhesion of the bowel to the edges of the wound has taken place.

THE LIVER.

The Liver is the largest gland in the body, and is situated in the upper and right part of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and extending into the left hypochondrium as far as the mammary line. In the male it weighs from fifty to sixty ounces; in the female, from forty to fifty. It is relatively much larger in the foetus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one thirty-sixth of the entire body-weight. Its greatest transverse measurement is from eight to nine inches. Vertically, near its lateral or right surface, it measures about six or seven inches, while its greatest antero-posterior diameter is on a level with the upper end of the right kidney and is from four to five inches. Opposite the vertebral column its measurement from before backward is reduced to about three inches. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its color is a dark reddish-brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape, it must be hardened *in situ*, and it will then be seen to present the appearance of a wedge, the base of which is directed

FIG. 511.—The liver. Upper surface. (Drawn from His's models.)

to the right and the thin edge toward the left. Symington describes its shape as that "of a right-angled triangular prism with the right angles rounded off." It possesses five surfaces, viz., superior, inferior, anterior, posterior, and lateral.

The superior and anterior surfaces are separated from each other by a thick rounded border, and are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the *suspensory* or *falciform ligament*, which divides the liver into two unequal parts, termed the right and left

lobes. Except along the line of attachment of this ligament to the liver, the superior and anterior surfaces are covered by peritoneum.

The *superior surface* (Fig. 511) comprises a part of both lobes, and, as a whole, is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, which corresponds with the position of the heart on the upper surface of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is separated from the under surface by a prominent sharp margin.

The *anterior surface* is large and triangular in shape, comprising also a part of both lobes. It is directed forward, and the greater part of it is in contact with the Diaphragm, which separates it from the right lower ribs and their cartilages. In the middle line it lies behind the ensiform cartilage, to the left of which it is protected by the seventh and eighth left costal cartilages. In the angle between the diverging rib cartilages of opposite sides the anterior surface is in contact with the abdominal wall. It is separated from the inferior surface by a sharp margin, and from the superior and lateral surfaces by thick rounded borders.

The *lateral or right surface* is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the left pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

Its *under or visceral surface* (Figs. 512, 513) is uneven, concave, directed downward and backward and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney and suprarenal capsule. The surface is divided by a longitudinal fissure into a right and a left lobe, and is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the blood-vessels and duct of the viscus. The under surface of the left lobe presents behind and to the left a depression where it is moulded over the cardiac part of the stomach, and to the right and near the centre a rounded eminence, the *tuber omentale*, which fits into the concavity of the lesser curvature, lying in front of the anterior layer of the lesser omentum. The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the gall-bladder, the *fossa vesicalis*; the portion to the left, the smaller of the two, is somewhat oblong in shape, its antero-posterior diameter being greater than its transverse. It is known as the *quadrate lobe*, and is in relation with the pyloric end of the stomach and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow concave impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the *impressio colica*, is produced by the hepatic flexure of the colon; the posterior, the *impressio renalis*, is occupied by the upper end of the right kidney. To the inner side of the latter impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the *impressio duodenalis*. Just in front of the vena cava is a narrow strip of liver tissue, the caudate lobe, which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. Immediately below it is the foramen of Winslow.

The *posterior surface* is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this uncovered portion is about three inches broad, and is in direct contact with the Diaphragm. It is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament. It is in the same way marked off from the under surface of the liver by the line of reflection of the lower layer of the coronary ligament. In its centre this posterior surface is deeply notched for the vertebral column and crura of the Diaphragm, and to the right

of this it is indented for the inferior vena cava, which is often partly imbedded in its substance. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area (*impressio suprarenalis*), the greater part of which is devoid of peritoneum; it lodges the right suprarenal capsule. To the left of the inferior vena cava is the *Spigelian lobe*, which lies between the fissure for the vena cava and the fissure for the ductus venosus. Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the *tuber papillare*. It is opposite the tenth and eleventh dorsal vertebræ, and rests upon the aorta and crura of the Diaphragm, being covered by the peritoneum of the lesser sac. The lobe is nearly vertical in position, and is directed backward: it is longer from above downward than from side to side, and is somewhat concave in the transverse direction. On the posterior surface to the left of the Spigelian lobe is a groove indicating the position of the œsophageal orifice of the stomach.

FIG. 512.—The liver. Posterior and inferior surfaces. (Drawn from His's models.)

The *inferior border* is thin and sharp, and marked opposite the attachment of the falciform ligament by a deep notch, the *umbilical notch*, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder. In adult males this border usually corresponds with the margin of the ribs in the right nipple line; but in women and children it usually projects below the ribs.

The *left extremity of the liver* is thin and flattened from above downward.

Fissures (Fig. 512).—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into five lobes. They are, the umbilical fissure, the fissure of the ductus venosus, the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava. They are arranged in the form of the letter H. The left limb of the H is known as the *longitudinal fissure*. The right limb is formed in front by the *fissure for the gall-bladder*, and behind by the *fissure for the inferior vena cava*; these two fissures are separated from each other by the caudate lobe. The connecting bar of the H is the *transverse or portal fissure*. It separates the quadrate lobe in front from the caudate and Spigelian lobes behind.

The *longitudinal fissure* is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ. It separates the right and left lobes; the transverse fissure joins it, at right angles, and divides it into two parts. The anterior part is called the *umbilical fissure*; it is deeper than the posterior, and lodges the umbilical vein in

the foetus, and its remains (the round ligament) in the adult; the posterior part contains the ductus venosus, and is known as the *fissure of the ductus venosus*. This fissure lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the *pons hepatis*.

The *fissure of the ductus venosus* is the back part of the longitudinal fissure, and is situated mainly on the posterior surface of the liver. It lies between the left lobe and the lobe of Spigelius. It lodges in the foetus the ductus venosus, and in the adult a slender fibrous cord, the obliterated remains of that vessel.

The *transverse* or *portal fissure* is a short but deep fissure, about two inches in length, extending transversely across the under surface of the left portion of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. By the older anatomists this fissure was considered the gateway (*porta*) of the liver; hence the large vein which enters at this fissure was called the *portal vein*. Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

FIG. 513.—Posterior and under surfaces of the liver. (From Ellis.)

The *fissure for the gall-bladder* (*fossa vesicalis*) is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to the right extremity of the transverse fissure.

The *fissure for the inferior vena cava* is a short, deep fissure, occasionally a complete canal, in consequence of the substance of the liver surrounding the vena cava. It extends obliquely upward from the lobus caudatus, which separates it from the transverse fissure, on the posterior surface of the liver, and separates the Spigelian from the right lobe. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelii, and the lobus caudatus, the last three being merely parts of the right lobe.

The *right lobe* is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper and anterior surfaces by the falciform ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava, which separate its left part into three smaller lobes—lobus Spigelii, lobus quadratus, and lobus caudatus. On it are seen four shallow impressions, one in front (*impressio colica*), for the hepatic flexure of the colon; a second behind (*impressio renalis*), for the right kidney; a third internal, between the last-named and the gall-bladder (*impressio duodenalis*), for the second part of the duodenum; and a fourth on its posterior surface, for the suprarenal capsule (*impressio suprarenalis*).

The *lobus quadratus*, or square lobe, is situated on the under surface of the right lobe, bounded in front by the inferior margin of the liver; behind by the transverse fissure; on the right, by the fissure of the gall-bladder; and on the left by the umbilical fissure.

The *lobus Spigelii* is situated upon the posterior surface of the right lobe of the liver. It looks directly backward, and is nearly vertical in direction. It is bounded, above, by the upper layer of the coronary ligament; below, by the transverse fissure; on the right, by the fissure for the vena cava; and, on the left, by the fissure for the ductus venosus. Its left upper angle forms part of the groove for the œsophagus.

The *lobus caudatus*, or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward, from the lower extremity of the lobus Spigelii to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava.

The *left lobe* is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex; its under surface is concave, and presents a shallow depression for the stomach (*gastric impression*). This is situated in front of the groove for the œsophagus, and is separated from the longitudinal fissure by the *omental tuberosity*, which lies against the small omentum and lesser curvature of the stomach.

Ligaments.—The liver is connected to the under surface of the Diaphragm and the anterior wall of the abdomen by five ligaments, four of which are peritoneal folds; the fifth is a round, fibrous cord, resulting from the obliteration of the umbilical vein. These ligaments are the falciform, two lateral, coronary, and round. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum (see page 902).

The *falciform ligament* (broad or suspensory ligament) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the sheath of the right Rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface. It consists of two layers of peritoneum closely united together. Its base or free edge contains the round ligament between its layers.

The *lateral ligaments* (Fig. 511), two in number, right and left, are triangular in shape. They are formed by the apposition of the upper and lower layers of the coronary ligament, and extend from the Diaphragm to the liver—the right being attached to the border between its lateral and inferior surfaces, the left, the lower of the two, to the upper surface of the left lobe, where it lies in front of the œsophageal opening in the Diaphragm.

The *coronary ligament* connects the posterior surface of the liver to the Diaphragm. It is formed by the reflection of the peritoneum from the Diaphragm on to the upper and lower margins of the posterior surface of the organ. The coro-

nary ligament consists of two layers, which are continuous on each side with the lateral ligaments; and, in front, with the falciform ligament. Between the layers a large triangular area is left uncovered by peritoneum, and is connected to the Diaphragm by firm areolar tissue.

The *round ligament* (*ligamentum teres*) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the longitudinal fissure on the under surface of the liver; on the posterior surface it is continued as the obliterated ductus venosus as far back as the inferior vena cava.

Vessels.—The vessels connected with the liver are also five in number: they are, the hepatic artery, the portal veins, the hepatic vein, the hepatic duct, and the lymphatics.

The *hepatic artery* and *portal vein*, accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum. The *hepatic duct*, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures is as follows: the hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They are enveloped in a loose areolar tissue, the *capsule of Glisson*, which accompanies the vessels in their course through the *portal canals* in the interior of the organ.

The *hepatic veins* convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, while that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the vena cava; that from the middle of the organ and lobus Spigelii having a straight course.

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, these veins remain widely open and solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct. The hepatic veins are destitute of valves.

Structure.—The substance of the liver is composed of lobules held together by an extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

The *serous coat* is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The *fibrous coat* lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is continuous with the capsule of Glisson, and on the surface of the organ with the areolar tissue separating the lobules.

The *lobules* form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland. They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower animals (for example, the pig) they are well-defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered round the smallest radicles (*sublobular*) of the hepatic veins, to which each is connected by means of a small branch which issues from the centre of the lobule (*intra-lobular*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of

areolar tissue in which is contained a plexus of vessels (the *interlobular plexus*) and ducts. In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 514).

Microscopic Appearance.—Each lobule is composed of a mass of cells (*hepatic cells*) surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single

FIG. 514.—Longitudinal section of a hepatic vein. (After Kiernan.)

FIG. 515.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

straight vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) *cells*, by which the secretion is formed; (2) *blood-vessels*, in close relation with the cells, containing the blood from which the secretion is derived; and (3) *ducts*, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

(1) The *hepatic cells* are of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the $\frac{1}{1000}$ to the $\frac{1}{2000}$ of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules.¹ As stated above, they are the chief agents in the secretion of the bile.

(2) *The Blood-vessels.*—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

¹ Delépine states that there are evidences of the arrangement of these cells in the form of columns, which form tubes with narrow lumina branching from terminal bile-ducts. This branching is evidenced by a divergence of the columns from lines extending between adjacent portal vessels. The columns of cells group round terminal bile-ducts, and not round the so-called intralobular veins. (*Lancet*, 1895, vol. i., p. 1254.)

The *hepatic artery*, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off *vaginal branches* which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membranes of the liver. It also gives off *capsular branches* which reach the surface of the organ, terminating in its fibrous coat in stellate plexuses. Finally it gives off *interlobular branches* which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this, lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The *portal vein* also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson's capsule, dividing into branches in its course, which finally break up into a plexus (the *interlobular plexus*) in the interlobular spaces. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 515). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, forming a number of converging vessels which are connected by transverse branches (Fig. 516). In the interstices of the network of vessels thus formed are situated,

FIG. 516.—Horizontal section of liver (dog).

as before said, the liver-cells: and here it is that, the blood being brought into intimate connection with the liver-cells, the bile is secreted. Arrived at the centre of the lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobules from apex to base and is called the *intralobular vein*. At the base of the lobule this vein opens directly into the *sublobular vein*, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned at page 619, converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.

(3) *The Ducts*.—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away.

Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed *intercellular biliary passages* or *bile-capillaries*. These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the angle where three or more liver-cells meet (Fig. 517), and it seems doubtful whether there is any delicate membrane

FIG. 517.—Section of liver.

FIG. 518.—A transverse section of a small portal canal and its vessels. (After Kiernan.) 1. Portal vein. 2. Interlobular branches. 3. Vaginal branches. 4. Hepatic duct. 5. Hepatic artery.

forming the wall of the channel. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (*interlobular*) between the lobules. From this plexus ducts are derived which pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (Fig. 518), join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Structure.—The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective-tissue coat, in which are muscle-cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells. In the larger ducts, which lie in the portal canals, there are a number of orifices disposed in two longitudinal rows, which were formerly regarded as the openings of mucous glands, but which are merely the orifices of tubular recesses. They occasionally anastomose, and from the sides of them saccular dilatations are given off.

Lymphatics of the Liver.—The lymphatics in the substance of the liver commence in lymphatic spaces around the capillaries of the lobules; they accompany the vessels of the interlobular plexus, often enclosing and surrounding them. These unite and form larger vessels, which run in the portal canals, enclosed in Glisson's capsule, and emerge at the portal fissure to be distributed in the manner described. Other superficial lymphatics form a close plexus, under the peritoneum, where this membrane covers the liver, and pass in various directions through the ligaments of the liver (page 634).

Nerves of the Liver.—The nerves of the liver derived from the pneumogastric and sympathetic enter the liver at the transverse fissure and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated enter the lobules and ramify between the cells.

The Excretory Apparatus of the Liver.

The excretory apparatus of the liver consists of (1) the *hepatic duct*, which, as we have seen, is formed by the junction of the two main ducts, which pass out of the liver at the transverse fissure, and are formed by the union of the bile-capil-

laries; (2) the *gall-bladder*, which serves as a reservoir for the bile; (3) the *cystic duct*, which is the duct of the gall-bladder; and (4) the *common bile-duct*, formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct.—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the right, the other from the left lobe; these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half, between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the ductus communis choledochus. The hepatic duct, as it descends from the transverse fissure of the liver, between the two layers of the lesser omentum, lies in company with the hepatic artery and portal vein.

The Gall-bladder is the reservoir for the bile; it is a conical or pear-shaped musculo-membranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is about four inches in length, one inch in breadth at its widest part, and holds from eight to ten drachms. It is divided into a fundus, body, and neck. The *fundus*, or broad extremity, is directed downward, forward, and to the right, and projects beyond the anterior border of the liver; the *body* and *neck* are directed upward and backward to the left. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

Relations.—The *body of the gall-bladder* is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the commencement of the transverse colon; and further back, with the upper end of the descending portion of the duodenum or sometimes with the pyloric end of the stomach or first portion of the duodenum. The *fundus* is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind with the transverse arch of the colon. The *neck* is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject: the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulæ, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—serous, fibrous and muscular, and mucous.

The *external* or *serous coat* is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surface.

The *fibro-muscular coat* is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscular fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The *internal* or *mucous coat* is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute rugæ, by the union of which numerous meshes are formed; the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of screw-like valve.

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the alimentary canal.

The **Cystic Duct**, the smallest of the three biliary ducts, is about an inch and a half in length. It passes obliquely downward and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. It lies in the gastro-hepatic omentum in front of the vena portæ, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a continuous spiral valve. When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a sacculated appearance.

The **Ductus Communis Choledochus**, or *common bile-duct*, the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, of the diameter of a goose-quill, and formed by the junction of the cystic and hepatic ducts.

It descends along the right border of the lesser omentum behind the first portion of the duodenum, in front of the vena portæ, and to the right of the hepatic artery; it then passes between the pancreas and descending portion of the duodenum, and running for a short distance along the right side of the pancreatic duct, near its termination, passes with it obliquely between the mucous and muscular coats. The two ducts open by a common orifice upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches below the pylorus.

Structure.—The coats of the large biliary ducts are an external or fibrous, and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts. The coats of the smallest biliary ducts, which lie in the interlobular spaces, are a connective-tissue coat, in which, according to Heidenhain, are muscle-cells arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells.

Surface Relations.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined in the middle line by the junction of the mesosternum with the ensiform cartilage; on the right side the line must be carried upward as far as the fifth rib cartilage in the line of the nipple and then downward to reach the seventh rib at the side of the chest. The *upper limit of the left lobe* may be defined by continuing this line to the left with an inclination downward to a point about two inches to the left of the sternum on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—i. e., the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are

distended and the Diaphragm descends very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight-lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ileum; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distension of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but can generally easily be replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastro-hepatic omentum and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen and tied and the margins of the laceration, if small, brought together and sutured by means of a blunt curved needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. When the laceration is extensive it must be packed with iodoform gauze, the end of which is allowed to hang out of the external wound. Abscess of the liver is of not infrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus it has been known to burst into the lungs and the pus coughed up, or into the stomach and the pus vomited; it may burst into the colon, or into the duodenum; or, by perforating the diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavities. Abscesses of the liver frequently require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and unless the peritoneum is adherent, sponges are packed all around the exposed liver surface and the abscess opened, if deeply seated preferably by the thermo-cautery. Hydatid cysts are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the *tænia echinococcus* being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid. Tumors of the liver have recently been subjected to surgical treatment by removal of a portion of the organ. The abdomen is opened and the diseased portion of liver exposed; the circulation is controlled by compressing the portal vein and the hepatic artery in the gastro-hepatic omentum and a wedge-shaped portion of liver containing the tumor removed; the divided vessels are ligated and the cut surfaces brought together and sutured in the manner directed above.

When the *gall-bladder* or one of its main ducts is ruptured, which may occur independently of laceration of the liver, death usually occurs from peritonitis. If the symptoms have led to the performance of a laparotomy and a rent is found, it should be sutured if small, or the gall-bladder removed if it is extensive. If the cystic duct is torn, its intestinal end must be closed and the gall-bladder removed. In rupture of either of the other ducts, the only thing which can be done is to provide for free drainage, in the hope that a biliary fistula may form.

The gall-bladder may become distended with bile in cases of obstruction of its duct or the common bile-duct, or from a collection of gall-stones within its interior, thus forming a large tumor. The swelling is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right semilunar line, commencing at the costal margin. The peritoneal cavity is opened, and, the tumor having been found, sponges are packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully

padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, and close the incision by fine sutures in two layers. After all obstruction has been removed, four courses are open to the surgeon: 1. The wound in the gall-bladder may be at once sewn up, the organ returned into the abdominal cavity, and the external incision closed. 2. The edges of the incision in the gall-bladder may be sutured to the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. 3. The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as cholecystenterostomy. 4. The gall-bladder may be completely removed.

THE PANCREAS.

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse mesocolon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. 3. By dividing the two layers of peritoneum, which descend from the great curvature of the stomach to form the great omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 488, page 900).

The **Pancreas** (*πανκρέας*, *all flesh*) is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and has been compared to a human or a dog's tongue: its right extremity being broad, is called the *head*—this is connected to the main portion of the organ, the *body*, by a slight constriction, the *neck*; while its left extremity gradually tapers to form the *tail*. It is situated

FIG. 519.—The pancreas and its relations.

transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches, its breadth is an inch and a half, and its thickness from half an inch to an inch, being greater at its right extremity and along its upper border. Its weight varies from two to three and a half ounces, but it may reach six ounces.

The *right extremity* or *head of the pancreas* (Fig. 519) is shaped like the head of a hammer, being elongated both above and below; it is flattened from before backward, and conforms to the whole concavity of the duodenum, which is slightly overlapped by it. The anterior surface near its left border is crossed by the

superior mesenteric vessels, and at its lower end it is crossed by the transverse colon and its mesocolon. Behind, the head of the pancreas is in relation with the inferior vena cava, the left renal vein, the right crus of the Diaphragm, and the aorta. The common bile-duct descends behind, between the duodenum and pancreas; and the pancreatico-duodenal artery descends in front between the same parts.

The *neck of the pancreas* is about an inch long, and passes upward and forward to the left, having the first part of the duodenum above it, and the termination of the fourth portion below. It lies in front of the commencement of the vena portæ, and is grooved on the right by the gastro-duodenal and superior pancreatico-duodenal arteries. The pylorus lies just above it.

The *body and tail of the pancreas* are somewhat prismatic in shape, and have three surfaces: anterior, posterior, and inferior.

The *anterior surface* is somewhat concave, and is covered by the posterior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. At its right extremity there is a well-marked prominence, called by His the *omental tuberosity*.

FIG. 520.—The duodenum and pancreas. The liver has been lifted up and the greater part of the stomach removed. (Testut.) a, Portal vein; b, Hepatic duct; c, Cystic duct; d, Hepatic artery; e, Right suprarenal capsule; f, Pyloric orifice; g, Right gastro-epiploic artery; h, Superior mesenteric vein; i, Left crus of diaphragm; j, Left suprarenal capsule; k, Splenic vein; l, Splenic artery; m, Duodeno-jejunal junction; A, B, C, D, The four portions of the duodenum.

The *posterior surface* is separated from the vertebral column by the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal capsule, the pillars of the Diaphragm, and the origin of the superior mesenteric artery.

The *inferior surface* is narrow, and lies upon the duodeno-jejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

The *superior border* of the body is blunt and flat to the right; narrow and sharp

to the left, near the tail. It commences to the right in the omental tuberosity, and is in relation with the celiac axis, from which the hepatic artery courses to the right just above the gland, while the splenic branch runs in a groove along this border to the left.

The *anterior border* is the position where the two layers of the transverse mesocolon separate: the one passing upward in front of the anterior surface, the other backward below the inferior surface.

The *lesser end* or *tail of the pancreas* is narrow; it extends to the left as far as the lower part of the inner aspect of the spleen.

Birmingham describes the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pan-

FIG. 521.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

creas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and running upward, forms a partial cap for the wide end of the stomach" ¹ (see Fig. 496).

The principal excretory duct of the pancreas, called the **pancreatic duct** or **canal of Wirsung**, from its discoverer, extends transversely from left to right through the substance of the pancreas. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from right to left through the body, it constantly receives the ducts of the various lobules composing the

¹ *Journal of Anatomy and Physiology*, vol. xxxi. pt. 1, p. 102.

gland. Considerably augmented in size, it reaches the neck, and turning obliquely downward, backward, and to the right, it comes into relation with the common bile-duct, lying to its left side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and terminates by an orifice common to it and the ductus communis choledochus upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches below the pylorus.

Sometimes the pancreatic duct and ductus communis choledochus open separately into the duodenum. Occasionally there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the *ductus pancreaticus accessorius* or *ductus Santorini*.

The pancreatic duct, near the duodenum, is about the size of an ordinary quill: its walls are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of cæcal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In some animals those cells which occupy the centre of the alveolus are spindle-shaped, and are known as the *centro-acinar cells of Langerhans*. The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar in shape and present two zones: an outer one clear and finely striated next the basement-membrane, and an inner granular one next the lumen. During activity the granular zone occupies the greater part of the cell: before the cells are called into action, while in a condition of rest, the outer or clear zone is the larger. In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells; this is termed the *paranucleus*, and is believed to be an extension from the nucleus. The connective tissue between the alveoli presents in certain parts collections of cells, which are termed *inter-alveolar cell-islets*.

Vessels and Nerves.—The *arteries of the pancreas* are derived from the splenic and the pancreatico-duodenal branches of the hepatic and the superior mesenteric. Its *veins* open into the splenic and superior mesenteric veins. Its *lymphatics* terminate in the lumbar glands. Its *nerves* are filaments from the splenic plexus.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—The pancreas presents but little of surgical importance. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cysts are also occasionally found in it, which may present in the epigastric region, above and to the right of the umbilicus, and may require opening and drainage. The fluid in them contains some of the elements of the pancreatic secretion and is very irritating, so that, if allowed to come in contact with the skin of the abdominal wall, it is likely to produce intractable eczema. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of diaphragmatic hernia. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of excision of the pylorus great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious results. According to Billroth, it is likely, in consequence of its peptonizing qualities, to dissolve the cicatrix of the stomach.

THE SPLEEN.

The **Spleen** belongs to that class of bodies which are known as *ductless glands*. It is probably related to the blood-vascular system, but in consequence of its anatomical relationship to the stomach and its physiological relationship to the liver it is convenient to describe it in this place. It is situated principally in the left hypochondriac region, its upper and inner extremity extending into the epigastric region; lying between the fundus of the stomach and the Diaphragm. It is the largest of the ductless glands, and measures some five or six inches in length. It is of an oblong, flattened form, soft, of very brittle consistence, highly vascular, and of a dark purplish color.

Surfaces.—The *external or phrenic surface* is convex, smooth, and is directed upward, backward, and to the left, except at its upper end, where it is directed slightly inward. It is in relation with the under surface of the Diaphragm, which separates it from the eighth, ninth, tenth, and eleventh ribs of the left side, and in part from the lower border of the left lung and pleura.

The *internal surface* is concave, and divided by a ridge into an anterior or larger, and a posterior or smaller portion.

The *anterior portion* of the internal surface or *gastric surface*, which is directed forward and inward, is broad and concave, and is in contact with the posterior wall of the great end of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the *hilum*. This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The *posterior portion* of the internal surface or *renal surface* is directed inward and downward. It is somewhat flattened, does not reach as high as the gastric surface, is considerably narrower than the latter, and is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal capsule.

The *upper end* is directed inward, toward the vertebral column, where it lies on a level with the eleventh dorsal vertebra. The *lower end*, sometimes termed the *basal surface*, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phreno-colic ligament, and is generally in contact with the tail of the pancreas. The *anterior border* is free, sharp, and thin, and is often notched, especially below. It separates the phrenic from the gastric surface. The *posterior border* is more rounded and blunter than the anterior. It separates the renal portion of the internal surface from the phrenic surface. It corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney. The *internal border* is the name sometimes given to the ridge which separates the renal and gastric portions of the internal surface.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule, and is held in position by two folds of this membrane: one, the *lienorenal ligament*, is derived from the layers of peritoneum forming the greater and lesser sacs, where they come into contact between the left kidney and the spleen. Between its two layers the splenic vessels pass (Fig. 489); the second, the *gastro-splenic omentum*, also formed of two layers, derived from the greater

FIG. 522.—The spleen, showing its gastric and renal surfaces. (Testut.)

and lesser sacs, respectively, where they meet between the spleen and stomach (Fig. 489). Between these two layers run the vasa brevia of the splenic artery and vein. It is also supported by the phreno-colic ligament, upon which its lower end rests (see page 902).

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually about five inches in length, three inches in breadth, and an inch or an inch and a half in thickness, and weighs about seven ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350: while in the adult it varies from 1 to 320 and 400. *In old age*, the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and

FIG. 523.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

after digestion, and varies considerably according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from 18 to 20 pounds.

Frequently in the neighborhood of the spleen, and especially in the gastro-splenic and great omenta, small nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *supernumerary* or *accessory spleens*. They vary in size from that of a pea to that of a plum.

Structure.—The spleen is invested by two coats—an external serous, and an internal fibro-elastic coat.

The *external* or *serous coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The *fibro-elastic coat* forms the framework of the spleen. It invests the organ, and at the hilum is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculae* (Fig. 524), are given off in all directions; these uniting, constitute the framework of the spleen. This resembles a sponge-like material, consisting of a number of small spaces or *areolae* formed by the trabeculae, which are given off from the inner surface of the capsule, or from the

sheaths prolonged inward on the blood-vessels. In these spaces or areolæ is contained the *splenic pulp*.

The proper coat, the sheaths of the vessels and the trabeculæ, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter considerably predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre, and in some mammalia (*e. g.* dog, pig, and cat) a very considerable amount, so that the trabeculæ appear to consist chiefly of muscular tissue. It is probably owing to this structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The *proper substance of the spleen* or *splenic pulp* is a soft mass of a dark reddish-brown color, resembling grumous blood. When examined, by means of a thin section, under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the *sustentacular* or *supporting cells of the pulp*. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolæ formed by the trabeculæ of the capsule; so that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than they are in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not become deeply stained with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amoeboid movements (Cohnheim). In many of them may be seen deep red

FIG. 524.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

or reddish-yellow granules of various sizes which present the characters of the hæmatin of the blood. Sometimes, also, unchanged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolæ formed by the framework of the spleen are thus filled

by a delicate reticulum of branched connective-tissue corpuscles the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

Blood-vessels of the Spleen.—The splenic artery is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance (Fig. 524), receiving sheaths from the involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The *arterioles*, supported by the minute trabeculæ, traverse the pulp in all directions in bundles or penicilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material.¹ This change is effected by the conversion of the connective tissue into a lymphoid tissue, the bundles of connective tissue becoming looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue, presents here and there thickenings of a spheroidal shape, the *Malpighian bodies of the spleen*. These bodies vary in size from about the $\frac{1}{100}$ of an inch to the $\frac{1}{25}$ of an inch in diameter. They are merely local expansions or hyperplasie of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to

FIG. 525.—Part of a Malpighian capsule of the spleen of man. (Klein and Noble Smith.) a, Arterial branch in longitudinal section. b, Adenoid tissue, still containing the lymph-corpuscles; only their nuclei are shown. c, Adenoid reticulum, the lymph-corpuscles accidentally removed.

tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than the other, and that, therefore, in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells.

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery

¹ According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a "solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath" (*Atlas of Histology*, p. 424).

of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amœboid movements, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions ;

FIG. 526.—Section of spleen, showing the termination of the small blood-vessels.

their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered, presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 526). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which commence much in the same way as the arteries terminate. Where a vein is about to commence the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillæ arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform epithelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from six or more branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the vena porta.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics originate in two ways,—*i. e.*, from the sheaths of the arteries and in the trabeculæ. The former accompany the blood-vessels, the latter pass to the superficial lymphatic plexus, which may be seen on the surface of the organ. The two sets communicate in the interior of the organ. They pass through the lymphatic glands at the hilum, and terminate in the thoracic duct.

The *nerves* are derived from branches of the right and left semilunar ganglia, and from the right pneumogastric nerve.

Surface Form.—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the eighth, ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions, viz., from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the midaxillary line" (Quain).

Surgical Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hæmorrhage, owing to the great vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear and the symptoms indicate danger to life laparotomy must be performed; and if the hæmorrhage cannot be stayed by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this may require removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, leukæmia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood-disease. In these cases the tumor may fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, and in leukæmic enlargement; but in these latter cases the operation is now regarded as unjustifiable, as every case in which it has been performed has terminated fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein. In applying the ligature care must be taken not to include the tail of the pancreas, and in lifting out the organ to avoid rupturing the capsule.

THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

THE Larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebræ, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of the epiglottis was a little above the level of the cartilage, between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral disks. According to Sappey, the average measurements of the adult larynx are as follows:

	In males.	In females.
Vertical diameter	44 mm.	36 mm.
Transverse diameter	43 “	41 “
Antero-posterior diameter	36 “	26 “
Circumference	136 “	112 “

Until puberty there is no marked difference between the larynx of the male and that of the female. In the latter its further increase in size is only slight, whereas in the former it is great; all the cartilages are enlarged, and the thyroid becomes prominent as the *pomum Adami* in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea.

The **Cartilages of the Larynx** are nine in number, three single, and three pairs:

Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula Laryngis.
Epiglottis.	Two Cuneiform.

The **thyroid** (*θυρεός*, a shield) is the largest cartilage of the larynx. It consists of two lateral lamellæ or alæ, united at an acute angle in front, forming a vertical projection in the middle line which is prominent above, and called the *pomum Adami*. This projection is subcutaneous, more distinct in the male than in the female, and occasionally separated from the integument by a bursa mucosa.

Each lamella is quadrilateral in form. Its *outer surface* presents an oblique ridge, which passes downward and forward from a tubercle, situated near the root of the superior cornu, to a small tubercle near the anterior part of the lower border. This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid

muscles, and the portion of cartilage included between it and the posterior border to part of the Inferior constrictor muscle.

The *inner surface* of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles, and the thyro-epiglottidean ligament.

The *upper border of the thyroid cartilage* is sinuously curved, being concave at its posterior part, just in front of the superior cornu, then rising into a convex outline, which dips in front to form the sides of a notch, the *thyroid notch*, in the middle line, immediately above the pomum Adami. This border gives attachment throughout its whole extent to the thyro-hyoid membrane.

The *lower border* is nearly straight in front, but behind, close to the cornu, is concave. It is connected to the cricoid cartilage, in and near the median line, by the middle portion of the crico-thyroid membrane; and, on each side, by the Crico-thyroid muscle.

The *posterior borders*, thick and rounded, terminate, above, in the *superior cornua*, and below, in the *inferior cornua*. The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in conical extremities, which give attachment to the lateral thyro-hyoid ligament. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and present, on their inner surfaces, a small oval articular facet for articulation with the side of the cricoid cartilage. The posterior border receives the insertion of the Stylo-pharyngeus and Palato-pharyngeus muscles on each side.

FIG. 527.—Side view of the thyroid and cricoid cartilages.

During infancy the alæ of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the *intra-thyroid cartilage*. This strip extends from the upper to the lower border of the cartilage in the middle line, and is distinguished from the alæ by, being more transparent and more flexible.

The *cricoid cartilage* is so called from its resemblance to a signet ring (*χιρικός*, a ring). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It consists of two parts: a quadrate portion, situated behind, and a narrow ring or arch, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion.

Its *posterior portion* is very deep and broad, and measures from above downward about an inch (2–3 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the œsophagus; and on either side a broad depression for the Crico-arytenoideus posticus muscle.

Its *anterior portion* is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (5–7 cm.); it affords attachment externally in front and at the sides to the Crico-thyroid muscles, and behind, to part of the Inferior constrictor.

At the point of junction of the posterior quadrate portion with the rest of the cartilage is a small round elevation, for articulation with the inferior cornu of the thyroid cartilage.

The *lower border* of the cricoid cartilage is horizontal, and connected to the upper ring of the trachea by fibrous membrane.

Its *upper border* is directed obliquely upward and backward, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the crico-thyroid membrane; at the sides, to the lateral portion of the same membrane and to the lateral Crico-arytenoid muscle; behind, it presents, in the middle, a shallow notch, and on each side of this is a smooth, oval surface, directed upward and outward, for articulation with the arytenoid cartilage.

The *inner surface* of the cricoid cartilage is smooth, and lined by mucous membrane.

The **arytenoid cartilages** are so called from the resemblance they bear, when approximated, to the mouth of a pitcher (*ἀρύταινα*, a pitcher). They are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx. Each cartilage is pyramidal in form, and presents for examination three surfaces, a base, and an apex.

The *posterior surface* is triangular, smooth, concave, and gives attachment to the Arytenoid muscle.

The *anterior or external surface* is somewhat convex and rough. It presents rather below its centre a transverse ridge, to the inner extremity of which is attached the false vocal cord, and to the outer part, as well as the surfaces above and below, is attached the Thyro-arytenoid muscle.

The *internal surface* is narrow, smooth, and flattened, covered by mucous membrane, and forms the lateral boundary of the respiratory part of the glottis.

The *base* of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: the *external*, which is short, rounded, and prominent, projects backward and outward, and is termed the *muscular process*, from receiving the insertion of the Posterior and Lateral crico-arytenoid muscles. The *anterior angle*, also prominent, but more pointed, projects horizontally forward, and gives attachment to the true vocal cord. This angle is called the *vocal process*.

The *apex* of each cartilage is pointed, curved backward and inward, and surmounted by a small conical, cartilaginous nodule, the *corniculum laryngis*.

The **cornicula laryngis** (*cartilages of Santorini*) are two small conical nodules, consisting of white fibro-cartilage, which articulate with the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are

FIG. 528.—The cartilages of the larynx. Posterior view.

attached the aryteno-epiglottidean folds. They are sometimes united to the arytenoid cartilages.

The **cuneiform cartilages** (*cartilages of Wrisberg*) are two small, elongated, cartilaginous bodies, placed one on each side, in the fold of mucous membrane which extends from the apex of the arytenoid cartilage to the side of the epiglottis (*aryteno-epiglottidean fold*); they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **epiglottis** is a thin lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue in front of the superior opening of the larynx. Its free extremity is broad and rounded; its attached part is long, narrow, and connected to the receding angle between the two alæ of the thyroid cartilage, just below the median notch, by a long, narrow ligamentous band, the *thyro-epiglottic ligament*. It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the *hyo-epiglottic ligament*.

Its *anterior* or *lingual surface* is curved forward, toward the tongue, and covered at its upper, free part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the *glossio-epiglottidean folds*. The depressions between the epiglottis and the base of the tongue, on either side of the median fold, are named the *valleculæ*. The lower part of its anterior surface lies behind the hyoid bone, the thyro-hyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

Its *posterior* or *laryngeal surface* is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the *tubercle* or *cushion*; when the mucous membrane is removed, the surface of the cartilage is seen to be studded with a number of small mucous glands, which are lodged in little pits upon its surface. To its sides the aryteno-epiglottidean folds are attached.

Structure.—The cuneiform cartilages, the epiglottis, and the apices of the arytenoids are composed of yellow fibro-cartilage, which shows little tendency to calcification; on the other hand, the thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone. The cornicula laryngis consist of white fibro-cartilage, which becomes osseous about the seventieth year.

Ligaments.—The ligaments of the larynx are *extrinsic*—i. e., those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*, those which connect the several cartilages of the larynx to each other.

The ligaments connecting the thyroid cartilage with the hyoid bone are three in number—the thyro-hyoid membrane, and the two lateral thyro-hyoid ligaments.

The *thyro-hyoid membrane*, or *middle thyro-hyoid ligament*, is a broad, fibro-elastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the posterior border of the body and greater cornua of the hyoid bone, thus passing behind the postero-inferior surface of the hyoid, and being separated from it by a synovial bursa, which facilitates the upward movement of the larynx during deglutition. It is thicker in the middle line than at either side, and is pierced, in the latter situation, by the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. Its anterior surface is in relation with the Thyro-hyoid, Sterno-hyoid, and Omo-hyoid muscles, and with the body of the hyoid bone.

The *two lateral thyro-hyoid ligaments* are rounded, elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in each.

The ligament connecting the epiglottis with the hyoid bone is the *hyo-epiglottic*. In addition to this extrinsic ligament, the epiglottis is connected to the tongue by the three glosso-epiglottidean folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis.

The *hyo-epiglottic ligament* is an elastic band, which extends from the anterior surface of the epiglottis, near its apex, to the upper border of the body of the hyoid bone.

The ligaments connecting the thyroid cartilage to the cricoid are also three in number—the crico-thyroid membrane, and the capsular ligaments.

The *crico-thyroid membrane* is composed mainly of yellow elastic tissue. It consists of three parts, a central, triangular portion and two lateral portions. The central part is thick and strong, narrow above and broadening out below. It connects together the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the Crico-thyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two crico-thyroid arteries. The lateral portions are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords, with which they are continuous.

The lateral portions are lined internally by mucous membrane, and covered by the lateral Crico-arytenoid and Thyro-arytenoid muscles.

A *capsular ligament* encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on each side. The articulation is lined by synovial membrane.

The ligaments connecting the arytenoid cartilages to the cricoid are two *capsular ligaments* and two *posterior crico-arytenoid ligaments*. The *capsular ligaments* are thin and loose capsules attached to the margin of the articular surfaces; they are lined internally by synovial membrane. The *posterior crico-arytenoid ligaments* extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The ligament connecting the epiglottis with the thyroid cartilage is the *thyro-epiglottic*.

The *thyro-epiglottic ligament* is a long, slender, elastic cord which connects the apex of the epiglottis with the receding angle of the thyroid cartilage, immediately beneath the median notch, above the attachment of the vocal cords.

The *crico-tracheal ligament* connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each other.

Interior of the Larynx.—The *cavity of the larynx* extends from its superior aperture to the lower border of the cricoid cartilage. It is divided into two parts by the projection/inward of the true vocal cords, between which is a narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity of the larynx above the true vocal cords, sometimes called the *vestibule*, is broad and triangular in shape, and corresponds to the interval between the *alæ* of the thyroid cartilage; it contains the false vocal cords, and between these and the true vocal cords are the ventricles of the larynx. The portion below the true vocal cords widens out, and is at first of an elliptical and lower down of a circular form, and is continuous with the tube of the trachea.

The *superior aperture of the larynx* (Fig. 529) is a triangular or cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages and the cornicula laryngis; and laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the sides of the epiglottis and the apices of the arytenoid cartilages: these are the *aryteno-epiglottidean folds*, on the margins of which the cuneiform cartilages form more or less distinct whitish prominences.

The *rima glottidis* is the elongated fissure or chink between the inferior or true

vocal cords in front, and between the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into an anterior interligamentous or *vocal* portion (*glottis vocalis*) and a posterior intercartilaginous or *respiratory* part (*glottis respiratoria*). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The vocal portion averages about three-fifths of the length of the entire aperture. It is the narrowest part of

FIG. 529.—Larynx, viewed from above. (Testut.)

the cavity of the larynx, and its level corresponds to the bases of the arytenoid cartilages. Its length, in the male, measures rather less than an inch (20–25 mm.); in the female it is shorter by 5 or 6 mm., or three lines. The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest—*i. e.*, when these structures are uninfluenced by muscular action, as in quiet respiration—the *glottis vocalis* is triangular, with its apex in front and its base behind, the latter being represented by a line about 8 mm. long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the *glottis respiratoria* is rectangular. During extreme adduction of the cords, as in the emission of a high note, the *glottis vocalis* is reduced to a linear slit by the apposition of the cords, while the *glottis respiratoria* is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outward, and the *glottis respiratoria* is triangular in shape, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the *glottis vocalis* diverging from before backward, those of the *glottis respiratoria* diverging from behind forward, the widest part of the aperture corresponding with the attachment of the cords to the vocal processes.¹

The *superior* or *false vocal cords*, so called because they are not directly concerned in the production of the voice, are two thick folds of mucous membrane, enclosing a narrow band of fibrous tissue, the *superior thyro-arytenoid ligament*, which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the anterior surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

¹ On the shape of the rima glottidis, in the various conditions of breathing and speaking, see Czermak, *On the Laryngoscope*, translated for the New Sydenham Society.

The *inferior* or *true vocal cords*, so called from their being concerned in the production of sound, are two strong bands (*inferior thyro-arytenoid ligaments*), covered on their surface by a thin layer of mucous membrane. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the two alæ of the thyroid cartilage, and behind to the anterior angle (vocal process) of the base of the arytenoid. Its lower border is continuous with the thin lateral part of the crico-thyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyro-arytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely thin, and closely adherent to its surface.

The *ventricle of the larynx* is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the superior vocal cord; below, by the straight margin of the true vocal cord; externally, by the mucous membrane covering the corresponding Thyro-arytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a cæcal pouch of mucous membrane of variable size, called the *laryngeal pouch*.

The *sacculus laryngis*, or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher: it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyro-arytenoid ligament: its laryngeal surface is covered by the Aryteno-epiglottideus inferior muscle (*Compressor sacculi laryngis*, Hilton); while its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles. These muscles compress the sacculus laryngis, and discharge the secretion it contains upon the chordæ vocales, the surfaces of which it is intended to lubricate.

Muscles.—The intrinsic muscles of the larynx are eight in number, five of which are the muscles of the vocal cords and rima glottidis, and three are connected with the epiglottis.

The five muscles of the vocal cords and rima glottidis are the—

Crico-thyroid.

Crico-arytenoideus posticus.

Crico-arytenoideus lateralis.

Arytenoideus.

Thyro-arytenoideus.

The *Crico-thyroid* is triangular in form, and situated at the fore part and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornua.

FIG. 530.—Vertical section of the larynx and upper part of the trachea.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the central part of the crico-thyroid membrane.

The *Crico-arytenoideus posticus* arises from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the outer angle (muscular process) of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.¹

The *Crico-arytenoideus lateralis* is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is inserted into the muscular process of the arytenoid cartilage in front of the preceding muscle.

The *Arytenoideus* is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border

of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The *oblique fibres*, the most superficial, form two fasciculi,

FIG. 531.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.

FIG. 532.—Interior of the larynx, seen from above. (Enlarged.)

which pass from the base of one cartilage to the apex of the opposite one. The *transverse fibres*, the deepest and most numerous, pass transversely across between the two cartilages; hence the *Arytenoideus* was formerly considered as three muscles, the transverse and the two oblique. A few of the oblique fibres are occasionally continued round the outer margin of the cartilage, and blend with the *Thyro-arytenoid* or the *Aryteno-epiglottideus* muscle.

The *Thyro-arytenoideus* is a broad, flat muscle, which lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the crico-thyroid membrane. Its

¹ Merkel, of Leipzig, has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the "*Musculus kerato-cricoides*." It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir William Turner (*Edinburgh Medical Journal*, Feb., 1860) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backward and downward, opposing in some measure the part of the *Crico-thyroid* muscle, which is connected to the anterior margin of the horn,

fibres pass backward and outward, to be inserted into the base and anterior surface of the arytenoid cartilage. This muscle consists of two fasciculi.¹ The *inner or inferior portion*, the thicker, is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it lies parallel with the true vocal cord, to which it is adherent. The *outer or superior fasciculus*, the thinner, is inserted into the anterior surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis, immediately beneath the mucous membrane.²

The muscles of the epiglottis are the—

Thyro-epiglottideus.

Aryteno-epiglottideus superior.

Aryteno-epiglottideus inferior.

The *Thyro-epiglottideus* is a delicate fasciculus, which arises from the inner surface of the thyroid cartilage, just external to the origin of the Thyro-arytenoid muscle, of which it is sometimes described as a part, and spreads over the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottidean fold, while the others are continued forward to the margin of the epiglottis (*Depressor epiglottidis*).

The *Aryteno-epiglottideus superior* consists of a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilages, and become lost in the fold of mucous membrane extending between the arytenoid cartilage and the side of the epiglottis (*aryteno-epiglottidean fold*).

The *Aryteno-epiglottideus inferior* (*Compressor sacculi laryngis*, Hilton) arises from the arytenoid cartilage, just above the attachment of the superior vocal cord; passing forward and upward, it spreads out upon the anterior surface of the epiglottis. This muscle is separated from the preceding by an indistinct areolar interval.³

Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the *Crico-arytenoidei postici*; and those which close it are the *Arytenoideus* and the *Crico-arytenoidei laterales*. 2. The muscles which regulate the tension of the vocal cords are the *Crico-thyroidei*, which tense and elongate them; and the *Thyro-arytenoidei*, which relax and shorten them. The *Thyro-epiglottideus* is a depressor of the epiglottis, and the *Aryteno-epiglottidei* constrict the superior aperture of the larynx, compress the sacculi laryngis, and empty them of their contents.

The *Crico-arytenoidei postici* separate the chordæ vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their vocal processes and the vocal cords attached to them become widely separated.

The *Crico-arytenoidei laterales* close the glottis by rotating the arytenoid cartilages inward so as to approximate their vocal processes.

The *Arytenoideus muscles* approximate the arytenoid cartilages, and thus close the opening of the glottis, especially at its back part.

The *Crico-thyroid muscles* produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by its extrinsic muscles; then the *Crico-thyroid muscles*, when they act, draw upward the front of the cricoid cartilage, and so depress

¹ Henle describes these two portions as separate muscles, under the names of External and Internal thyro-arytenoid.

² Luschka has described a small but fairly constant muscle as the *Arytenoideus rectus*. It is attached below to the posterior concave surface of the arytenoid cartilage, beneath the *Arytenoideus* muscle, and, passing upward, emerges at the upper border of this muscle, and is inserted into the posterior surface of the cartilage of Santorini (*Anatomy*, by Hyrtl, page 718).

³ *MUSCULUS TRITICEO-GLOSSUS*. Bochdalek, jun. (*Prager Vierteljahrsschrift*, 2d part, 1866), describes a muscle hitherto entirely overlooked, except a brief statement in Henle's *Anatomy*, which arises from the nodule of cartilage (*corpus triticeum*) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the *Hyo-glossus* muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.

the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyro-arytenoidei muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The *Thyro-epiglottidei* may depress the epiglottis; they assist in compressing the sacculus laryngis. The *Aryteno-epiglottideus superior* constricts the superior aperture of the larynx, when it is drawn upward, during deglutition. The *Aryteno-epiglottideus inferior*, together with some fibres of the *Thyro-arytenoidei*, compress the sacculus laryngis.

The **Mucous Membrane of the Larynx** is continuous above with that lining the mouth and pharynx, and it is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the anterior part of the upper surface of the epiglottis, to which it is closely adherent, and forms the aryteno-epiglottidean folds which form the lateral boundaries of the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms, by its reduplication, the chief part of the superior or false vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The fore part of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryteno-epiglottidean folds, and the true vocal cords are covered by stratified squamous epithelium; all the rest of the laryngeal mucous membrane is covered by columnar ciliated cells.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the free edges of the vocal cords.

Vessels and Nerves.—The *arteries of the larynx* are the laryngeal branches derived from the superior and inferior thyroid. The *veins* accompany the arteries; those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The *lymphatics* consist of two sets, superior and inferior. The former accompany the superior laryngeal artery and pierce the thyro-hyoid membrane, to terminate in the glands situated near the bifurcation of the common carotid artery. The latter pass through the crico-thyroid membrane, and open into one or two glands lying either in front of that membrane or to the side of the cricoid cartilage. The nerves are derived from the internal and external laryngeal branches of the superior laryngeal nerve, from the inferior or recurrent laryngeal, and from the sympathetic. The internal laryngeal nerve is almost entirely sensory, but some motor filaments are said to be carried by it to the *Arytenoideus* muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryteno-epiglottidean folds, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal nerve supplies the Crico-thyroid muscle. The recurrent laryngeal passes upward under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Crico-thyroid and part of the *Arytenoideus*. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibres ascend to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryteno-epiglottidean folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

THE TRACHEA (Fig. 533).

The **trachea**, or windpipe, is a cartilaginous and membranous cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the fourth, or sometimes the fifth,

FIG. 533.—Front view of cartilages of larynx; the trachea and bronchi.

dorsal vertebra, where it divides into two bronchi, one for each lung. The trachea measures about four inches and a half in length; its diameter, from side to side, is from three-quarters of an inch to an inch, being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroidea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and more superficially, by the anastomosing branches between the anterior jugular veins: in the thorax it is

covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the oesophagus; laterally, *in the neck*, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, *in the thorax*, it lies in the upper part of the interpleural space (superior mediastinum), and is in relation on the right to the pleura and right vagus, and near the root of the neck to the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, the left common carotid and subclavian arteries.

The **Right Bronchus**, wider, shorter, and more vertical in direction than the left, is about an inch in length, and enters the right lung opposite the fifth dorsal vertebra. The vena azygos major arches over it from behind; and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the *eparterial* branch, because it is given off above the right pulmonary artery. The bronchus now passes below the artery, and is known as the *hyarterial* branch. It divides into two branches for the middle and lower lobes.

The **Left Bronchus** is smaller and longer than the right, being nearly two inches in length. It enters the root of the left lung, opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the oesophagus, the thoracic duct, and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. The left bronchus has no branch corresponding to the *eparterial* branch of the right bronchus, and therefore it has been supposed by some that there is no upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung.

When the bronchi enter the lung they appear to divide into nearly equal branches at the root of the lung, but a somewhat similar arrangement to what is found in many animals may be made out where each bronchus passes downward and backward toward the extremity of the lower lobe, giving off four branches at intervals in two directions, dorsally and ventrally, and, in addition, accessory branches, which arise from the front of the bronchus and pass mesially and dorsally into the inferior lobe. In the right bronchus the *first ventral* branch supplies the middle lobe, the other three and all the dorsal going to the lower lobe; in the left bronchus, the *first ventral* supplies the superior lobe, and all the others, both ventral and dorsal, go to the lower lobe.

If a transverse section of the trachea is made a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 534), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea more frequently falls into the right bronchus.¹

Structure.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

The **cartilages** vary from sixteen to twenty in number: each forms an imperfect ring, which surrounds about two-thirds of the cylinder of the trachea, being imperfect behind, where the tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth, and half a line in thickness. Their outer surfaces are flattened, but internally they are convex,

¹ Reigel asserts that the entry of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also *Med.-Chir. Trans.*, vol. lxxi, p. 121.

from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The *first cartilage* is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The *last cartilage* is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, imbedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The *muscular fibres* are disposed in two layers, longitudinal and transverse. The *longitudinal fibres* are the most external, and consist merely of a few scattered longitudinal bundles of fibres.

The *transverse fibres* (Trachealis muscle, Todd and Bowman), the most internal, form a thin layer, which extends transversely between the ends of the cartilages and the intervals between them at the posterior part of the trachea. The muscular fibres are of the unstriped variety.

The *Mucous membrane* is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it consists of areolar and lymphoid tissue, and presents a well-marked basement-membrane, supporting a layer of columnar, ciliated epithelium, between the deeper ends of which are smaller triangular cells, the bases of which, often branched, are attached to the basement-membrane. These triangular cells are mucus-secreting, and may be seen as goblet- or chalice-cells when their contents have been discharged. In the deepest part of the mucous membrane, and especially between the mucous and submucous layers, longitudinally arranged fibres are very abundant and form a distinct layer.

The *Tracheal glands* are found in great abundance at the posterior part of the trachea. They are racemose glands, and consist of a basement-membrane lined by columnar mucus-secreting cells. They are situated at the back of the trachea, outside the layer of muscular tissue, between it and the outer fibrous layer. Their excretory ducts pierce the muscular and inner fibrous layers, and pass through the submucous and mucous layers to open on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The *veins* terminate in the thyroid venous plexus. The *nerves* are derived from the pneumogastric and its recurrent branches and from the sympathetic.

FIG. 534.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can be readily distinguished. In the receding angle below the chin the hyoid bone can easily be made out (see page 126), and a finger's breadth below it is the *pomum Adami*, the prominence between the upper borders of the two *alæ* of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends in the neck it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope, the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic ligaments; the superior aperture of the larynx, bounded on either side by the aryteno-epiglottidean folds, in which may be seen two rounded eminences corresponding to the cornicula and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—*Foreign bodies* often find their way into the air-passages. These may be either large soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnoea from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, more often the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "oedema of the glottis." This effusion does not extend below the level of the vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as "clergyman's sore throat." It is due to the dryness induced by the large amount of cold air drawn into the air-passages during prolonged speaking, which incites increased activity in the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened in two different situations: through the crico-thyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cricoid cartilage with the upper ring of the trachea (*laryngo-tracheotomy*).

Laryngotomy is anatomically the more simple operation: it can readily be performed, and should be employed in those cases where the air-passages require opening in an emergency for the relief of some sudden obstruction to respiration. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the crico-thyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy tube introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut, through the superficial structures, and thus to open at once the air-passages. It will be seen, however, that in operating in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphe divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bosc has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in the opposite conditions.

A portion of the larynx or the whole of it has been removed for malignant disease, *laryngectomy*. The results which have been obtained from the removal of the whole of it have not been very satisfactory, and the cases in which the operation is justifiable are very few. It may be removed by a median incision through the soft parts, freeing the cartilage from the muscles and other structures in front, separating the larynx from the trachea below, and dissecting off the deeper structure from below upward.

THE PLEURÆ.

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the *pleura*, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes, is called the *pleura pulmonalis* (visceral layer of pleura), while that which lines the inner surface of the chest is called the *pleura costalis* (parietal layer of pleura). The space between these two layers is called the *cavity of the pleura*, but it must be borne in mind that in the healthy condition the two layers are in contact, and there is no real cavity until the lung becomes collapsed and a separation of it from the wall of the chest takes place. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate from each other. The two pleuræ do not meet in the middle line of the chest, excepting anteriorly opposite the second and third pieces of the sternum—a space being left between them, which contains all the viscera of the thorax excepting the lungs: this is the *mediastinum*.

Reflections of the Pleura (Fig. 535).—Commencing at the sternum, the pleura passes outward, lines the costal cartilages, the inner surface of the ribs and

Intercostal muscles, and at the back part of the thorax passes over the thoracic ganglia and their branches, and is reflected upon the sides of the bodies of the

FIG. 535.—A transverse section of the thorax, showing the relative position of the viscera and the reflections of the pleura.

vertebræ, where it is separated by a narrow interval, the *posterior mediastinum*, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular fold descends vertically by the side of the posterior mediastinum to the Diaphragm. This fold is the broad ligament of the lung, the *ligamentum latum pulmonis*, and serves to retain the lower part of that organ in position. From the root the pleura may be traced over the convex surface of the lung, the summit and base, and also over the sides of the fissures between the lobes on to its inner surface and the front part of its root; from this it is reflected on to the pericardium, and from it to the back of the sternum. Below, it covers the upper surface of the Diaphragm, and extends in front as low as the costal cartilage of the seventh rib; at the side of the chest, to the lower border of the tenth rib on the left side, and to the upper border of the same rib on the right side; and behind, it reaches as low as the twelfth rib, and sometimes even as low as the transverse process of the first lumbar vertebra. Above, its apex projects, in the form of a *cul-de-sac*, through the superior opening of the thorax into the neck, extending from one to two inches above the margin of the first rib, and receives the summit of the corresponding lung; this sac is strengthened, according to Sibson, by a dome-like expansion of fascia, attached in front to the posterior border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the *Scaleni* muscles.

In the front of the chest, where the parietal layer of the pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a considerable extent. At the upper part of the chest, behind the manubrium, they are not in contact; the point of reflection being represented by a line drawn from the sterno-clavicular articulation to the mid-point of the junction of the manubrium to the body of the sternum. From this point the two pleuræ descend in close contact to the level of

the fourth costal cartilage. Here the line of reflection on the right side is continued onward in nearly a straight line to the lower end of the gladiolus and then turns outward, while on the left side the line of reflection diverges outward, so that opposite the seventh cartilage it is about three-quarters of an inch from the left border of the sternum. It, however, always extends considerably farther over the pericardium than the corresponding lung. The lower limit of the pleura is on a considerably lower level than the lower limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the Internal intercostal muscles. Moreover, in ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of pleural reflection, with the result that the costal and diaphragmatic pleura are here in contact, the narrow slit between the two being termed the *phrenico-costal sinus*. A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the *costo-mediastinal sinus*.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm: throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Vessels and Nerves.—The *arteries of the pleura* are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiac, and bronchial. The *veins* correspond to the arteries. The *lymphatics* are very numerous. The *nerves* are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleura pulmonalis.

Surgical Anatomy.—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

THE MEDIASTINUM.

The **Mediastinum** is the space left in the median portion of the chest by the non-approximation of the two pleuræ. It extends from the sternum in front to the spine behind, and contains all the viscera in the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an upper portion, above the upper level of the pericardium, which is named the *Superior mediastinum* (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the *middle mediastinum*; that part which is in front of the pericardium, the *anterior mediastinum*; and that part which is behind the pericardium, the *posterior mediastinum*.

The **superior mediastinum** is that portion of the interpleural space which lies above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebræ behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra, and laterally by the lungs and pleuræ. It contains the origins of the Sterno-hyoid and Sterno-thyroid muscles and the lower ends of the Longi colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus gland and some lymphatic glands.

The anterior mediastinum is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above obliquely downward and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left

FIG. 536.—The posterior mediastinum.

costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three lymphatic glands (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

The middle mediastinum is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of

the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

FIG. 537.—Transverse section through the upper margin of the third dorsal vertebra. (Braune.)

The **posterior mediastinum** (Fig. 536) is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the oesophagus, thoracic duct, and some lymphatic glands.

THE LUNGS.

The **Lungs** are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and other contents of the mediastinum. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces (Fig. 538).

The *apex* forms a tapering cone which extends into the root of the neck about an inch to an inch and a half above the level of the first rib.

The *base* is broad, concave, and rests upon the convex surface of the Diaphragm, which separates the right lung from the upper surface of the right lobe of the liver and the left lung from the upper surface of the left lobe of the liver, the stomach, and spleen; its circumference is thin, and projects for some distance into the phrenico-costal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

The *external* or *thoracic surface* is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front.

The *inner surface* is concave. It presents in front a depression corresponding

to the convex surface of the pericardium, and behind a deep fissure (the hilum pulmonis) which gives attachment to the root of the lung.

The *posterior border* is rounded and broad, and is received into the deep concavity on either side of the spinal column. It is much longer than the anterior border, and projects, below, into the phrenico-costal sinus.

The *anterior border* is thin and sharp, overlaps the front of the pericardium, and is projected into the costo-mediastinal sinus of the pleura. The anterior

FIG. 538.—Front view of the heart and lungs.

border of the right lung is almost vertical; that of the left presents, below, an angular notch, the *incisura cardiaca*, into which the heart and pericardium are received.

Each lung is divided into two lobes, an upper and a lower, by a long and deep fissure, which extends from the upper part of the posterior border of the organ about three inches from its apex, downward and forward to the lower part of its anterior border. This fissure penetrates nearly to the root. In the right lung the upper lobe is partially subdivided by a second and shorter fissure, which extends almost horizontally forward from the middle of the preceding to the anterior margin of the organ, marking off a small triangular portion, the middle lobe.

The *right lung* is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The Root of the Lungs.—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies

behind the superior vena cava and ascending portion of the aorta and below the vena azygos major. That of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz., the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the right side their position is—bronchus, pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. It should be noted that the entire right bronchus does not lie above the right pulmonary artery, but only its eparterial branch (see page 966), which passes to the upper lobe of the right lung; the divisions of the bronchus for the middle and lower lobes lie below the artery.

The *weight* of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being in the former as 1 to 37, in the latter as 1 to 43. The specific gravity of the lung-tissue varies from 0.345 to 0.746, water being 1000.

The *color* of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior border of the lung is usually darker than the anterior.

The *surface* of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The *substance* of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The *serous coat* is derived from the pleura; it is thin, transparent, and invests the entire organ as far as the root.

The *subserous areolar tissue* contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules.

The *parenchyma* is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the foetus. The lobules vary in size; those on the surface are large, of pyramidal form, the base turned toward the surface; those in the interior, smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

The *bronchus*, upon entering the substance of the lung, divides and subdivides bipinnately, throughout the entire organ. Sometimes three branches arise together, and occasionally small lateral branches are given off from the sides of a main trunk. Each of the smaller subdivisions of the bronchi enters a pulmonary lobule, and is termed a *lobular bronchial tube* or *bronchiole*. Its wall now begins to present irregular dilatations, *air-cells* or *alveoli*, at first sparingly and on one side of the tube only, but as it proceeds onward these dilatations become more numerous and surround the tube on all sides, so that it loses its cylindrical character. The

bronchiole now becomes enlarged, and is termed the *atrium* or *alveolar passage*; from it are given off, on all sides, ramifications, called *infundibula*, which are closely beset in all directions by *alveoli* or *air-cells*. Within the lungs the bronchial tubes are circular, not flattened, and present certain peculiarities of structure.

Changes in the Structure of the Bronchi in the Lungs.—1. *In the Lobes of the Lungs.*—In the lobes of the lungs the following changes take place. The *cartilages* are not imperfect rings, but consist of thin laminæ, of varied form and size, scattered irregularly along the sides of the tube, being most distinct at the points of division of the bronchi. They may be traced into tubes, the diameter of which is only one-fourth of a line. Beyond this point the tubes are wholly membranous. The fibrous coat is continued into the smallest ramifications of the bronchi. The muscular coat is disposed in the form of a continuous layer of annular fibres, which may be traced upon the smallest bronchial tubes, and consists of the unstriped variety of muscular tissue. The mucous membrane lines the bronchi and its ramifications throughout, and is covered with columnar ciliated epithelium.

In the Lobules of the Lung.—In the lobular bronchial tubes and in the infundibula the following changes take place: The muscular tissue begins to disappear, so that in the infundibula there is scarcely a trace of it. The fibrous coat becomes thinner, and degenerates into areolar tissue. The epithelium becomes non-ciliated and flattened. This occurs gradually; thus, in the lobular bronchioles patches of non-ciliated flattened epithelium may be found scattered among the columnar ciliated epithelium; then these patches of non-ciliated flattened epithelium become more and more numerous, until in the infundibula and air-cells all the epithelium is of the non-ciliated pavement variety. In addition to these flattened cells, there are small polygonal granular cells in the air-sacs, in clusters of two or three, between the others.

The air-cells are small, polyhedral recesses composed of a fibrillated connective tissue and surrounded by a few involuntary muscular and elastic fibres. Free in their cavity are to be seen under the microscope granular, rounded, amœboid cells (eosinophile leucocytes), often containing carbonaceous particles. The air-cells are well seen on the surface of the lung, and vary from $\frac{1}{100}$ th to $\frac{1}{70}$ th of an inch in diameter, being largest on the surface at the thin borders and at the apex, and smallest in the interior.

The *pulmonary artery* conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network upon the walls of the intercellular passages and air-cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

The *pulmonary capillaries* form plexuses which lie immediately beneath the mucous membrane in the walls and septa of the air-cells and of the infundibula. In the septa between the air-cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves;¹ their walls are also exceedingly thin. The arteries of neighboring lobules are independent of each other, but the veins freely anastomose together.

The *pulmonary veins* commence in the pulmonary capillaries, the radicles coalescing into larger branches, which run along through the substance of the lung, independently from the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the organ. Finally they open into the left auricle of the heart, conveying oxygenated blood to be eventually distributed to all parts of the body by the aorta.

The *bronchial arteries* supply blood for the nutrition of the lung; they are derived from the thoracic aorta or from the upper aortic intercostal arteries, and,

¹ The meshes are only 0.002''' to 0.008''' in width, while the vessels are 0.003''' to 0.005''' (Kölliker, *Human Microscopic Anatomy*).

accompanying the bronchial tubes, are distributed to the bronchial glands, and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network.

The *bronchial vein* is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary vein. It terminates on the right side in the vena azygos major, and on the left side in the superior intercostal or left upper azygos vein.

The *lymphatics* consist of a superficial and deep set: they terminate at the root of the lung, in the bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, upon which they are lost. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downward and inward across the sterno-clavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura (see page 971) extends farther down than the lung, so that it may be wounded, and a wound pass through its cavity into the Diaphragm, and even injure the abdominal viscera, without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outward.

The position of the great fissure in the right lung may be indicated by a line drawn from the fourth dorsal vertebra round the side of the chest to the anterior margin of the lung opposite the seventh rib, and the smaller or secondary fissure by a line drawn from the preceding where it bisects the mid-axillary line to the junction of the fourth costal cartilage to the sternum. The great fissure in the left lung is a little higher, extending from the third dorsal vertebra round the side of the chest to reach the anterior margin of the lung opposite the sixth costal cartilage.

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—

i.e., the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment

FIG. 539.—Thoracic contents seen from behind. (Joessel.)

of compression, the air is unable to escape from the lung, which is not able to recede, and consequently gives way.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the pleura costalis and pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular

tissue of the parietes of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes, therefore, the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety; that is to say, from external wounds, from stabs, gunshot injuries, and such like, in which cases air passes either from the wound of the lung or from an external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes one form of *hernia* of the lung. Another form of *hernia* of the lung occurs, though very rarely, after wounds of the chest wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

THE THYROID GLAND.

The **thyroid gland** is classified with the thymus, suprarenal capsules, and spleen, under the head of *ductless glands*—i. e., glands which do not possess an excretory duct. From its situation in connection with the trachea and larynx, the thyroid body is usually described with those organs, although it takes no part in the function of respiration. It is situated at the front and sides of the neck, and consists of two lateral lobes connected across the middle line by a narrow transverse portion, the *isthmus*.

The weight of the gland is somewhat variable, but is usually about one ounce. It is somewhat heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The lobes are conical in shape, the apex of each being directed upward and outward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring.

The *external or superficial surface* is convex, and covered by the skin, the superficial and deep fascia, the Sterno-mastoid, the anterior belly of the Omo-hyoid, the Sterno-hyoid and Sterno-thyroid muscles, and beneath the last muscle by the pre-tracheal layer of the deep fascia, which forms a capsule for the gland.

The *deep or internal surface* is moulded over the underlying structures, viz., the thyroid and cricoid cartilages, the trachea, the inferior constrictor and posterior part of the Crico-thyroid muscles, the œsophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves.

Its *anterior border* is thin, and inclines obliquely from above downward and inward toward the middle line of the neck, while the *posterior border* is thick and overlaps the common carotid artery. Each lobe is about two inches in length, its greatest width is about one inch and a quarter, and its thickness about three quarters of an inch.

The *isthmus* connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea. Its situation presents, however, many variations, a point of importance in the operation of tracheotomy. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the Sterno-hyoid. Across its upper border runs a branch of the superior thyroid artery; at its lower border are the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the *pyramid*, occasionally arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly the left, and ascends as high as the hyoid bone. It is occasionally quite detached, or divided into two or more parts, or altogether wanting.

A few muscular bands are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle, which was named by Sommerring the *Levator glandulæ thyroideæ*.

Small detached portions of thyroid tissue (*accessory thyroid*) are sometimes found above the isthmus, and their presence is readily explained by a reference to the manner in which the gland is developed. They represent isolated portions of the median thyroid rudiment. (See section on Embryology.)

Structure.—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance and imperfectly divides it into masses of irregular form and size. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Baber, who has published some important observations on the minute structure of the thyroid,¹ the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (*e. g.*, young

FIG. 540.—Minute structure of thyroid. From a transverse section of the thyroid of a dog. (Semi-diagrammatic.) (Baber.)

dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which, though differing somewhat in shape in different animals, have always a tendency to assume a columnar form. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the hæmoglobin, which is thus set free from the colored corpuscles. Baber has also described in the thyroid gland of the dog large round cells ("parenchymatous cells"), each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicle. These lymph-spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the

¹ "Researches on the Minute Structure of the Thyroid Glands," *Phil. Trans.*, part iii., 1881.

arteries which they accompany, and communicates with a network in the capsule of the gland. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

Vessels and Nerves.—The *arteries* supplying the thyroid are the superior and inferior thyroid, and sometimes an additional branch (*thyroidea media* or *ima*) from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The *veins* form a plexus on the surface of the gland and on the front of the trachea, from which arise the superior, middle, and inferior thyroid veins, the two former terminating in the internal jugular, the latter in the innominate vein. The *lymphatics* are numerous, of large size, and terminate in the thoracic and right lymphatic ducts. The *nerves* are derived from the middle and inferior cervical ganglia of the sympathetic.

Surgical Anatomy.—The thyroid gland is subject to enlargement, which is called goitre. This may be due to hypertrophy of any of the constituents of the gland. The simplest (parenchymatous goitre) is due to an enlargement of the follicles. The *fibroid* is due to increase of the interstitial connective tissue. The *cystic* is that form in which one or more large cysts are formed from dilatation and possibly coalescence of adjacent follicles. The *pulsating goitre* is where the vascular changes predominate over the parenchymatous, and the vessels of the gland are especially enlarged. Finally, there is *exophthalmic goitre* (Graves's disease), where there is great vascularity and often pulsation, accompanied by exophthalmos, palpitation, and rapid pulse.

For the relief of these growths various operations have been resorted to, such as injection of tincture of iodine or perchloride of iron, especially applicable to the cystic form of the disease, ligature of the thyroid arteries, excision of the isthmus, and extirpation of the whole or a part of the gland. This latter operation is one of difficulty, and when the entire gland has been removed the operation has been followed by a condition resembling myxœdema. In removing the organ great care must be taken to avoid tearing the capsule, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured before an attempt is made to remove the mass, and in ligaturing the inferior thyroids the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligature. A large number of cases of what were formerly supposed to be goitre are now known to be cases of adenomatous enlargement, where an adenoma, starting in one part of the gland, gradually spreads and involves the whole organ.

Parathyroids.—These are small rounded, brownish-red bodies, with an average diameter of about a quarter of an inch, situated in or near the thyroid gland, from which, however, they differ in structure, being composed of masses of cells arranged in a more or less columnar fashion with numerous intervening capillaries. They are divided from their situation into *external* and *internal*. The former, usually two in number, are situated, one on each side, in relation to the postero-internal surface of the lateral lobe; sometimes they are duplicated. The latter, also usually two in number, are placed one in each lateral lobe, generally near its mesial surface.

THE THYMUS GLANDS.

The **thymus gland** is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow, and gradually dwindles, until at puberty it has almost disappeared. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, soft, and lobulated on its surfaces. It is about two inches in length, one and a half in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The *cortical portion* is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the *medullary portion* there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has recently made the important observation that hæmoglobin is found in the thymus either in cysts or in cells situated near to or forming part

FIG. 541.—Minute structure of thymus gland. Upper portion of the thymus of a fetal pig of 2" in length, showing the bud-like lobuli and glandular elements. 2. of the concentric corpuscles. This hæmoglobin varies from granules to masses exactly resembling colored blood-corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing hæmoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuscles.

Vessels and Nerves.—The *arteries* supplying the thymus are derived from the internal mammary and from the superior and inferior thyroid. The *veins* terminate in the left innominate vein and in the thyroid veins. The *lymphatics*

are of large size, arise in the substance of the gland, and are said to terminate in the internal jugular vein. The *nerves* are exceedingly minute; they are derived

The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.) A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large colorless cell containing small oval masses of hæmoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone. B. Colored blood-corpuscles.

from the pneumogastric and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

THE URINARY ORGANS.

THE KIDNEYS.

THE Kidneys, two in number, are situated in the back part of the abdomen, and are for the purpose of separating from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat and loose areolar tissue. Their upper extremity is on a level with the upper border of the twelfth dorsal vertebra, their lower extremity on a level with the third lumbar. The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver.

Each kidney is about four inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from $4\frac{1}{2}$ ounces to 6 ounces; in the adult female, from 4 ounces to $5\frac{1}{2}$ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has a characteristic form. It is flattened on its sides and presents at one part of its circumference a hollow. It is larger at its upper than its lower extremity. It presents for examination two surfaces, two borders, and an upper and lower extremity.

Its *anterior surface* is convex, looks forward and outward, and is partially covered by peritoneum. The right kidney in its upper three-fourths is in contact with the posterior part of the under surface of the right lobe of the liver, on which it produces a concave impression, the *impressio renalis* (page 918). Toward its inner border it is covered by the second part of the duodenum, while its lower and outer part is in relation with the hepatic flexure of the colon. The relation of the second part of the duodenum to the front of the right kidney is a varying one. The left kidney is covered above by the posterior surface of the stomach, below the stomach by the pancreas, behind which are the splenic vessels. Its lower half is in contact with some of the coils of the small intestine and sometimes with the third part of the duodenum. Near its outer border the anterior surface lies behind the spleen and the splenic flexure of the colon.

The kidneys are partly covered in front by peritoneum and partly uncovered. On the right kidney, the *hepatic area*, that is to say that portion of the kidney which produces the renal impression on the liver, is covered by peritoneum, which therefore separates the kidney from the liver: the *duodenal* and *colic areas* are not peritoneal, and these structures are connected to the kidney by loose connective tissue; at the lower and inner extremity is a small area, the *mesocolic area*, which is covered by a layer of peritoneum of the greater sac and by the colic vessels. On the left kidney, the *gastric area* is covered by the peritoneum of the lesser sac; the *pancreatic* and *colic areas* are non-peritoneal: while, as on the right side, at the lower and inner extremity, is an area, *mesocolic*, which is covered by the peritoneum of the greater sac and by the colic vessels.

The posterior surface of the kidney is flatter than the anterior and is directed backward and inward. It is entirely devoid of peritoneal covering, being imbedded in areolar and fatty tissue. It lies upon the Diaphragm, the anterior layer of the lumbar aponeurosis, the external and internal arcuate ligaments, the Psoas

and Transversalis muscles, one or two of the upper lumbar arteries, the last dorsal, ilio-hypogastric, and ilio-inguinal nerves. The right kidney rests upon the twelfth rib, the left usually on the eleventh and twelfth. The Diaphragm separates the kidney from the pleura as it dips down to form the phrenico-costal sinus, but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the external arcuate ligament, and when this is the case the perirenal areolar tissue is in immediate apposition with the diaphragmatic pleura.

The *external border* is convex, and is directed outward and backward, toward the postero-lateral wall of the abdomen. On the left side it is in contact, at its upper part, with the spleen.

The *internal border* is concave, and is directed forward and a little downward. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the *hilum*, and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

The *superior extremity*, directly slightly inward as well as upward, is thick and rounded, and is surmounted by the suprarenal capsule, which covers also a small portion of the anterior surface.

The *inferior extremity*, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part. By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter *behind and below* the other vessels; the hilum will then be directed to the side to which the kidney belongs.

FIG. 543.—Vertical section of kidney.

General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue which forms a firm, smooth covering to the organ. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue and small blood-vessels are torn through. Beneath this coat a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the fibrous coat is stripped off, the surface of the kidney is found to be smooth and even and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed around the vessels and the excretory duct (Fig. 543). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance.

This central cavity is called the *sinus*, and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the *hilum* (before mentioned), which is situated at that part of the cavity which is not surrounded

by kidney-structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus. The excretory duct, or *ureter*, after entering, dilates into a wide, funnel-shaped sac named the *pelvis*. This divides into two or three tubular divisions, which subdivide into several short, truncated branches named *calices* or *infundibula*, all of which are contained in the central cavity of the kidney. The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance.

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz. of an external granular investing part, which is called the *cortical portion*; and of an internal part, the *medullary portion*, made up of a number of dark-colored pyramidal masses, with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillæ which project into the interior of the calices.

The cortical substance is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. The part separating the sides of any two pyramids through which the arteries and nerves enter, and the veins and lymphatics emerge, from the kidney, is called a *cortical column* or *column of Bertin* (A, A', Fig. 543); while that portion which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (marked by the dotted line extending from A to A' in Fig. 543), is called a *cortical arch*, the depth of which varies from a third to half an inch.

The *medullary substance*, as before stated, is seen to consist of red-colored, striated, conical masses, the *pyramids of Malpighi*, the number of which, varying from eight to eighteen, corresponds to the number of lobes of which the organ in the foetal state is composed. The base of each pyramid is surrounded by a cortical arch, and directed toward the circumference of the kidney; the sides are contiguous with the cortical columns; while the apex, known as the *papilla* or *mammilla* of the kidney, projects into one of the calices of the ureter, each calyx receiving two or three papillæ.

These two parts, *cortical* and *medullary*, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

Minute Anatomy.—The *tubuli uriniferi*, of which the kidney is for the most part made up, commence in the cortical portion of the kidney, and, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths (Fig. 544), so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of

one of the papillæ is examined with a lens, it will be seen to be studded over with a number of small depressions, from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the *tubuli uriniferi*, which terminate in this situation. They commence in the cortical portion of the kidney as the *Malpighian*

FIG. 544.—Plan of uriniferous tubes. A, A. Malpighian bodies. B, B. Margin of medullary structure. C, C, C. Loops of Henle. D, D, D. Straight tubes cut off. E. Commencing straight tubes. F. Termination of straight tube.

bodies, which are small rounded masses, varying in size, but average about $\frac{1}{120}$ of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a *Malpighian tuft*, and a membranous envelope, the *Malpighian capsule*, or *capsule of Bowman*, which latter is a small pouch-like commencement of a uriniferous tubule.

The *Malpighian tuft*, or vascular glomerulus, is a network of convoluted capillary blood-vessels held together by scanty connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the *afferent vessel*, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the resulting vein, the *efferent vessel*, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 545). The *Malpighian* or *Bowman's capsule*, which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squamous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (Fig. 546). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a con-

FIG. 545.—Minute structure of kidney.

FIG. 546.—Malpighian body.

tinuous layer of cells, which varies in size according to the state of secretion and the amount of fluid present in it. The cells, as above stated, are squamous in the adult, but in the foetus and young subject they are polyhedral or even columnar.

The *tubuli uriniferi*, commencing in the Malpighian bodies, in their course present many changes in shape and direction, and are contained partly in the medullary and partly in the cortical portions of the organ. At their junction with the Malpighian capsule they present a somewhat constricted portion which is termed the *neck*. Beyond this the tube becomes convoluted, and pursues a considerable course in the cortical structure, constituting the *proximal convoluted tube*. After a time the convolutions disappear, and the tube approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tube has been called the *spiral tube of Schachowa*. Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the *descending limb of Henle's loop*. Bending on themselves, they form a kind of loop, the *loop of Henle*, and, reascending, become suddenly enlarged and again spiral in direction, forming the *ascending limb of Henle's loop*, and re-enter the cortical

structure. This portion of the tube does not present a uniform calibre, but becomes narrower as it ascends and irregular in outline. As a narrow tube it enters the cortex and ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the *irregular tubule*; it terminates in a convoluted tube which exactly resembles the proximal convoluted tubule; and is called the *distal convoluted tubule*. This again terminates in a narrow *curved tube*, which enters the straight or collecting tube.

Each *straight*, otherwise called a *collecting* or *receiving*, tube commences by a small orifice on the summit of one of the papillæ, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups called *medullary rays*, several of these groups corresponding to a single pyramid. The tubes in the centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the

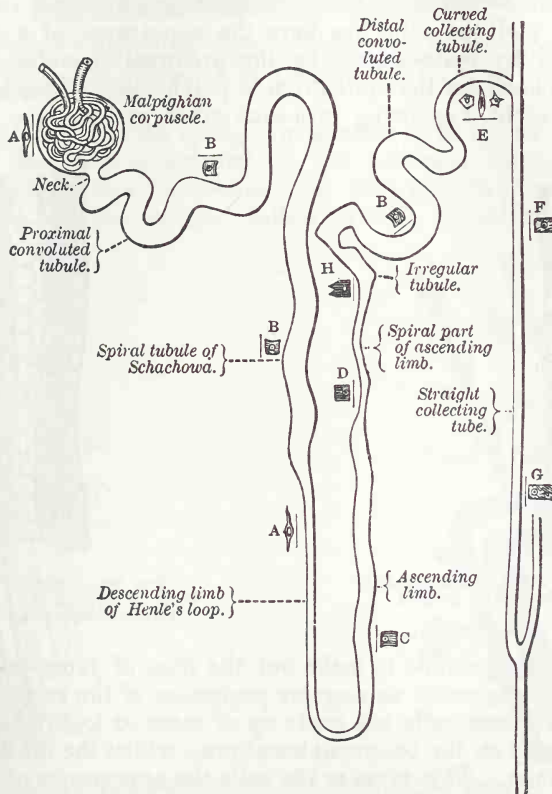

FIG. 547.—Uriniferous tube. For the sake of clearness the epithelial cells have been represented more highly magnified than the tubes in which they are contained.

cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ, and the bases are applied to the medullary portion. These are termed the *pyramids of Ferrein*. As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termina-

tion at the orifices on the apices of the pyramids of Malpighi, and that the urine, the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. To recapitulate: the tube first presents a constricted portion, (1) the *neck*. 2. It forms a wide convoluted tube, the *proximal convoluted tube*. 3. It becomes spiral, the *spiral tubule of Schachowa*. 4. It enters the medullary structure as a narrow, straight tube, the *descending limb of Henle's loop*. 5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the *ascending limb of Henle's loop*. 6. It now becomes irregular and angular in outline, the *irregular tubule*. 7. It then becomes convoluted, the *distal convoluted tubule*. 8. Diminishing in size, it forms a curve, the *curved tubule*. 9. Finally, it joins a straight tube, the *straight collecting tube*, which is continued downward through the medullary substance to open at the apex of a pyramid.

The Tubuli Uriniferi: their Structure.—The tubuli uriniferi consist of basement membrane lined with epithelium. The epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus (Fig. 547 A). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement membrane unlined by epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused

together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation (Heidenhain) (Fig. 547, B). In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Figs. 547, A, 548). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 547, c). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell:

¹ From *Handbook for the Physiological Laboratory*.

at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen (Fig. 547, D). In the irregular tubule the cells undergo a still farther change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules (Fig. 547, H). In

the distal convoluted tubule the epithelium appears to be somewhat similar to that which has been described as existing in the proximal convoluted tubule, but presents a peculiar refractive appearance (Fig. 547, B). In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly

as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral (Fig. 547, E).

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Figs. 549, 550), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes (Fig. 547, F and G).

The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery, a large offset of the abdominal aorta. Previously to entering the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsules, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the *inferior renal artery*. The branches of the renal artery whilst in the sinus give off a few twigs for the nutrition of the surrounding tissues, and terminate in the *arteriæ propriæ renales*, which enter the kidney proper in the columns of Bertin. Two of these pass to each pyramid of Malpighi and run along its sides for its entire length, giving off as they advance the afferent vessels of the Malpighian bodies in the columns. Having arrived at the bases of the pyramids, they make a bend in their course, so as to lie between the bases of the pyramids and the cortical arches, where they break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

The *first set*, the *interlobular arteries* (Figs. 551, 552, B), are given off at right angles from the side of the *arteriæ propriæ renales* looking toward the cortical substance, and, passing directly outward between the pyramids of Ferrein, they reach the capsule, where they terminate in the capillary network of this part. In their outward course they give off lateral branches; these are the *afferent vessels* for the Malpighian bodies (see page 988), and, having pierced the capsule, end in the Malpighian tufts. From each tuft the corresponding renal efferent arises, and, having made its egress from the capsule near to the point where the afferent vessel entered, breaks up into a number of branches which form a dense *venous plexus* around the adjacent urinary tubes (Fig. 553).

uses found in that situation. They are called the *arteriolæ rectæ* (Figs. 551, 552, F).

The *renal veins* arise from *three sources*—the veins beneath the capsule, the plexuses around the convoluted tubules in the cortical arches, and the plexuses situated at the apices of the pyramids of Malpighi. The veins beneath the capsule are stellate in arrangement, and are derived from the capillary network of the capsule, into which the terminal branches of the interlobular arteries break up. These join to form the *venæ interlobulares*, which pass inward *between* the pyramids of Ferrein, receive branches from the plexuses around the convoluted tubules, and, having arrived at the bases of the Malpighian pyramids, join with the *venæ rectæ*, next to be described (Figs. 551, 552, b).

The *Venæ Rectæ* are branches from the plexuses at the apices of the medullary pyramids, formed by the terminations of the *arteriolæ rectæ*. They pass outward in a straight course between the tubes of the medullary structure, and joining, as above stated, the *venæ interlobulares*, form the proper renal veins (Figs. 551, 552, f).

These vessels, *Venæ Propriæ Renales*, accompany the arteries of the same name, running along the entire length of the sides of the pyramids; and, having received

in their course the efferent vessels from the Malpighian bodies in the cortical structure adjacent, quit the kidney substance to enter the sinus. In this cavity they inosculate with the corresponding veins from the other pyramids to form the *renal vein*, which emerges from the kidney at the hilum and opens into the inferior vena cava, the left being longer than the right, from having to cross in front of the abdominal aorta.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, but their exact mode of termination is not known.

The *lymphatics* consist of a superficial and deep set which terminate in the lumbar glands.

Connective Tissue, or Intertubular Stroma.—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

Surface Form.—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly*: “1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart’s ligament has one-third of the kidney to its outer side and two-thirds to its inner side—i. e. between this line and the median line of the body.” In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. *Posteriorly*: The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: “1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for $2\frac{1}{4}$ inches. 3. A line from the lower end of the first transversely outward for $2\frac{1}{4}$ inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described.”

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

Surgical Anatomy.—Malformations of the kidney are not uncommon. There may be an entire absence of one kidney, though, according to Morris, the number of these cases is “excessively small”: or there may be congenital atrophy of one kidney, when the kidney is very small, but usually healthy in structure. These cases are of great importance, and must be duly taken into account, when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be only joined together at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body or they may be completely united, forming a disc-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher or lower than normal or removed farther from the spine than usual or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed. It is then known as a *floating kidney*. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum which then passes backward to the spine as a double layer, forming a mesonephron, which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in

the tissues by which it is surrounded, either moving in its capsule or else moving with the capsule in the perinephric tissues. This condition is known as *movable kidney*, and is more common in the female than the male. Other malformations are the persistence of the foetal lobulation; the presence of two pelves or two ureters to the one kidney. In some rare instances a third kidney may be present.

The kidney is imbedded in a large quantity of loose fatty tissue, and is but partially covered by peritoneum; hence rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is, in the majority of cases, outside the peritoneal cavity. Occasionally the kidney may be bruised by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient hæmaturia, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess may burst into the pleura, constituting empyema; into the colon or bladder; or may point externally in the groin or loin. Tumors of the kidney, of which, perhaps, sarcoma in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation, with sometimes faintness.

The kidney is mainly held in position by the mass of fatty matter in which it is embedded. If this fatty matter is loose or lax or is absorbed, the kidney may become movable and may give rise to great pain. This condition occurs, therefore, in badly nourished people or in those who have become emaciated from any cause, and is more common in women than in men. It must not be confounded with the *floating kidney*: this is a congenital condition due to the development of a mesonephron, which permits the organ to move more or less freely. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

The kidney has, of late years, been frequently the seat of surgical interference. It may be exposed for exploration or the evacuation of pus (nephrotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when movable or floating (nephro-raphy); or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The operation is best performed by a lumbar incision, except in cases of very large tumors or of wandering kidneys with a loose mesonephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique, a vertical, or a transverse incision. Perhaps the preferable, as affording the best means for exploring the whole surface of the kidney, is an incision from the tip of the last rib backward to the edge of the Erector spinæ. This incision must not be quite parallel to the rib, but its posterior end must be at least three-quarters of an inch below it, lest the pleura be wounded. This cut is quite sufficient for an exploration of the organ. Should it require removal, a vertical incision can be made downward to the crest of the ilium, along the outer border of the Quadratus lumborum. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the External oblique muscle of the abdomen, and the outer border of the Latissimus dorsi; the Internal oblique and the posterior aponeurosis of the Transversalis muscle; the outer border of the Quadratus lumborum, and the deep layer of the lumbar fascia, and the transversalis fascia. The fatty tissue around the kidney is now exposed to view, and must be separated by the fingers or a director in order to reach the kidney.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with. If the incision is made in the linea alba, the kidney is reached from the inner side of the colon, and the vessels running to supply it must necessarily be interfered with. The incision is made of varying length according to the size of the kidney, commencing just below the costal arch. The abdominal cavity is opened. The intestines are held aside, and the outer layer of the mesocolon incised, so that the fingers can be introduced behind the peritoneum and the renal vessels sought for. These are then to be ligatured: if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and the ureter divided, and the latter tied, or if thought necessary, stitched to the edge of the wound.

THE URETERS.

The Ureters are the two tubes which conduct the urine from the kidneys into the bladder. They commence within the sinus of the kidney by a number of short truncated branches, the *calices* or *infundibula*, which unite either directly

or indirectly to form a dilated pouch, the *pelvis*, from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The *calices* are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillæ, their number is generally less than the pyramids themselves, the former being from seven to thirteen, whilst the latter vary from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the *pelvis* or dilated portion of the ureter. The portion last mentioned, where the *pelvis* merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum (see Fig. 507, page 924).

The *ureter proper* is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the *pelvis* of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region into the cavity of the *pelvis* where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice, after having passed obliquely for nearly an inch between its muscular and mucous coats.

Relations.—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the spermatic vessels; the right is crossed by the branches of the mesenteric arteries, which are distributed to the ascending, and the left by those for the descending colon; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery, lying behind the ileum on the *right* side and the sigmoid flexure of the colon on the *left*. In the *pelvis* it enters the posterior false ligament of the bladder, below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter passes along the side of the neck of the uterus and upper part of the vagina. At the base of the bladder it is situated about two inches from its fellow: lying, in the male, about an inch and a half from the vesical orifice of the urethra, at one of the posterior angles of the trigone.

Structure.—The *ureter* is composed of three coats—a fibrous, muscular, and mucous.

The *fibrous coat* is the same throughout the entire length of the duct, being continuous at one end with the capsule of the kidney at the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.

In the *pelvis* of the kidney the muscular coat consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the *ureter proper* the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal, a middle circular, and an internal layer, less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillæ of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of “transitional” epithelium. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with a concave margin on their outer surface, into which fits the rounded end of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement membrane.

The *arteries* supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The *nerves* are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

Surgical Anatomy.—Subcutaneous rupture of the ureter is not a common accident, but occasionally occurs from a sharp, direct blow on the abdomen, as from the kick of a horse. It may be either torn completely across or only partially divided, and, as a rule, the peritoneum escapes injury. If torn completely across, the urine collects in the retroperitoneal tissues; if it is not completely divided, the lumen of the tube may become obstructed and hydro-nephrosis or pyo-nephrosis result. The ureter may be accidentally wounded in some abdominal operations; if this should happen, the divided ends must be sutured together, or, failing to accomplish this, the upper end must be implanted into the bladder or the intestine.

THE SUPRARENAL CAPSULES.

The **Suprarenal Capsules** belong to the class of ductless glands. They are two small flattened bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely

FIG. 554.—Vertical section of the suprarenal capsule. From Elberth, in Stricker's *Manual*.

FIG. 555.—Minute structure of suprarenal capsule.

FIG. 556.—Minute structure of suprarenal capsule.

detected: their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is from one to one and a half drachms each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body. The *right suprarenal* is roughly triangular in shape, its angles pointing upward, downward, and outward. It presents two surfaces for examination, an anterior and a posterior. The *anterior surface* presents two areas, separated by a furrow, the *hilum*: one area occupying about one-third of the whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the posterior surface of the right lobe of the liver, and along its inner border with the inferior vena cava; the remaining area is elevated, and is divided into a non-peritoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by peritoneum forming the hepatorenal fold. The *posterior surface* is slightly convex, and rests upon the Diaphragm. The *base* is concave, and is in contact with the upper end and the adjacent part of the anterior surface of the kidney. The *left suprarenal* is crescentic in shape, its concavity being adapted to the upper end of the left kidney. It presents an inner border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its *anterior surface* presents two areas: an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. Its *posterior surface* presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, while the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm. The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Small accessory suprarenals are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure.—On making a perpendicular section, the gland is seen to consist of two substances—external or cortical, and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep yellow color. The medullary substance is soft, pulpy, and of a dark brown or black color, whence the name *atriliary capsules* formerly given to these organs. In the centre is often seen a space, not natural, but formed by breaking down after death of the medullary substance.

The **cortical portion** consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that there the section somewhat resembles a net; this is termed the *zona glomerulosa*; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise, the *zona fasciculata*. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the *zona reticularis*. These processes or trabeculæ, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not infrequently fat-globules. These groups of cells do not entirely fill the spaces in which they are contained, but between them and the trabeculæ of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the group. The lymph path is supposed

to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

In the **medullary portion** the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla: this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerges as a single vessel from the centre of the gland.

The *arteries* supplying the suprarenal capsules are numerous and of large size; they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The *suprarenal vein* returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it opens on the right side into the inferior vena cava, on the left side into the renal vein.

The *lymphatics* terminate in the lumbar glands.

The *nerves* are exceedingly numerous, and are derived from the solar and renal plexuses, and, according to Bergmann, form the phrenic and pneumogastric nerves. They enter the lower and inner part of the capsule, traverse the cortex, and terminate round the cells of the medulla. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE CAVITY OF THE PELVIS.

The **cavity of the pelvis** is that part of the general abdominal cavity which is below the level of the linea ilio-pectinea and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Pyriformis muscle, and the great sacro-sciatic ligaments; in front and at the sides by the ossa pubis and ischia, covered by the Obturator muscles; above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the urinary bladder, the rectum, and some of the generative organs peculiar to each sex, and some convolutions of the small intestines; they are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.

THE BLADDER.

The **bladder** is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distention of the organ. *During infancy* it is conical in shape, and projects above the upper border of the ossa pubis into the hypogastric region. *In the adult*, when quite empty and contracted, it is cup-shaped, and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is

placed deeply in the pelvis, flattened from before backward, and reaches as high as the upper border of the symphysis pubis. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity; and when greatly distended it is ovoid in shape, rising into the abdominal cavity, and often extending nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the symphysis pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its capacity is said to be greater

Fig. 557.—Vertical section of bladder, penis, and urethra.

than in the male.¹ When moderately distended, it measures about five inches in length, and three inches across, and the ordinary amount which it contains is about a pint.

The bladder is divided for purposes of description into a superior, an antero-inferior, and two lateral surfaces, a base or fundus and a summit or apex.

The superior or abdominal surface is entirely free, and is covered throughout by peritoneum. It looks almost directly upward into the abdominal cavity, and extends in an antero-posterior direction from the apex to the base of the bladder. It is in relation with the small intestine and sometimes with the sigmoid flexure, and in the female, with the uterus. On each side, in the male, a portion of the

¹ According to Henle, the bladder is considerably smaller in the female than in the male.

vas deferens is in contact with the hinder part of this surface, lying beneath the peritoneum.

The antero-inferior or pubic surface looks downward and forward. In the undistended condition it is uncovered by peritoneum, and is in relation with the Obturator internus muscle on each side, with the recto-vesical fascia, and anterior true ligaments of the bladder. It is separated from the body of the pubis by a triangular interval, the *space of Retzius*, occupied by fatty tissue. As the bladder

FIG. 558.—Vertical median section of the male pelvis. (Henle.)

ascends into the abdominal cavity during distention the distance between its apex and the umbilicus is necessarily diminished, and the urachus is thus relaxed; so that, instead of passing directly upward to the umbilicus, it descends first on the upper part of the anterior surface of the bladder, and then, curving upward, ascends on the back of the abdominal wall. The peritoneum, which follows the urachus, thus comes to form a pouch of varying depth between the anterior surface of the viscus and the abdominal wall. Thus, when the bladder is distended, the upper part of its anterior surface is in relation to the urachus and is covered by peritoneum. The lower part of its anterior surface, a distance of about two inches above the symphysis pubis, is devoid of peritoneum, and is in contact with the abdominal wall.

The lateral surfaces are covered behind and above by peritoneum, which extends as low as the level of the obliterated hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from

the Levatores ani muscles and walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the recto-vesical fascia by a broad expansion on either side, the *lateral true ligaments*. The vas deferens crosses the hinder part of the lateral surface obliquely, and passes between the ureter and the bladder.

The *fundus* or *base* is directed downward and backward, and is partly covered by peritoneum and partly uncovered. In the male the upper portion, to within about an inch and a half of the prostate, is covered by the recto-vesical pouch of peritoneum. The lower part is in direct contact with the anterior wall of the second part of the rectum and the vesiculæ seminales and vasa deferentia. The ureters enter the bladder at the upper part of its base, about two inches above the prostate gland.

FIG. 559.—Frontal section of the lower part of the abdomen. Viewed from the front. (Braune.)

The portion of the bladder in relation with the rectum corresponds to a triangular space, bounded, below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; and on each side, by the vesicula seminalis and vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. *In the female*, the base of the bladder is connected to the anterior aspect of the cervix uteri by areolar tissue, and is adherent to the anterior wall of the vagina. Its upper surface is separated from the anterior surface of the body of the uterus by the utero-vesical pouch of peritoneum.

The so-called *neck (cervix)* of the bladder is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck,

but the bladder suddenly contracts to the opening of the urethra. In the male its direction is oblique in the erect posture, and it is surrounded by the prostate gland. In the female its direction is obliquely downward and forward.

The **urachus** is the obliterated remains of the tubular canal of the *allantois*, which exists in the embryo, and a portion of which becomes expanded to form the bladder (see section on Embryology). It passes upward, from the apex of the bladder, between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscular fibres. On each side of it is placed a fibrous cord, the obliterated portion of the hypogastric artery, which, passing upward from the side of the bladder, approaches the urachus above its summit. In the infant, at birth, it is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The *anterior true ligaments (pubo-prostatic)* extend from the back of the ossa pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland. These ligaments are formed by the recto-vesical fascia, and contain a few muscular fibres prolonged from the bladder.

The *lateral true ligaments*, also formed by the recto-vesical fascia, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate and to the sides of the base of the bladder.

The *urachus* is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, at its attachment to the bladder, and becomes narrower as it ascends.

The *false ligaments of the bladder* are two posterior, two lateral, and one superior.

The *two posterior* pass forward, in the male, from the sides of the rectum; in the female, from the sides of the uterus, to the posterior and lateral aspect of the bladder: they form the lateral boundaries of the recto-vesical fold of the peritoneum, and contain the obliterated hypogastric arteries, and the ureters, together with vessels and nerves.

The *two lateral ligaments* are reflections of the peritoneum, from the iliac fossæ and lateral walls of the pelvis to the sides of the bladder.

The *superior ligament (ligamentum suspensorium)* is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It is carried off from the bladder by the urachus and the obliterated hypogastric arteries.

Structure.—The bladder is composed of four coats—serous, muscular, sub-mucous, and mucous.

The *serous coat* is partial, and derived from the peritoneum. It invests the superior surface and the upper part of the lateral surfaces and base, and is reflected from these parts on to the abdominal and pelvic walls.

The *muscular coat* consists of three layers of unstriped muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The *fibres of the external longitudinal layer* arise from the posterior surface of the body of the os pubis in both sexes (*musculi pubo-vesicalis*), and in the male from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female.

At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the *detrusor urinæ muscle*.

The *middle circular layers* are very thin and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, round the cervix and commencement of the urethra, they are disposed in a thick circular layer, forming the *sphincter vesicæ*, which is continuous with the muscular fibres of the prostate gland.

The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are inserted, by means of a fibrous process, into the middle lobe of that organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue connecting together the muscular and mucous coats, and intimately united to the latter.

The *mucous coat* is thin, smooth, and of a pale rose color. It is continuous above through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. It is connected loosely to the muscular coat by a layer of areolar tissue, and is therefore thrown into folds or *rugæ* when the bladder is empty. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei; beneath these, a stratum of large club-shaped cells with the narrow extremity directed downward and wedged in between smaller spindle-shaped cells, containing an oval nucleus (Figs. 560, 561). There are no true glands in the mucous mem-

FIG. 560.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

FIG. 561.—Deep layers of epithelium of bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)

brane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Objects seen on the Inner Surface.—Upon the inner surface of the bladder are seen the orifices of the ureters, the trigone, and the commencement of the urethra.

The Orifices of the Ureters.—These are situated at the base of the trigone, being distant from each other about two inches; they are about an inch and a half from the base of the prostate and the commencement of the urethra.

The *trigonum vesicæ*, or *trigone vesical*, is a triangular smooth surface, with the apex directed forward, situated at the base of the bladder, immediately behind the urethral orifice. It is paler in color than the rest of the interior, and never presents any *rugæ*, even in the collapsed condition of the organ, owing to the intimate adhesion of its mucous membrane to the subjacent tissue. It is bounded at each posterior angle by the orifice of the ureter, and in front by the orifice of the urethra.

Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, called the *uvula vesicæ*. It is formed by a thickening of the submucous tissue.

The *arteries* supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small visceral branches to the bladder.

The *veins* form a complicated plexus round the neck, sides, and base of the bladder, and terminate in the internal iliac vein.

The *lymphatics* form two plexuses, one in the muscular and another in the submucous coat; they are most numerous in the neighborhood of the trigone. They accompany the blood-vessels, and ultimately terminate in the internal iliac glands.

The *nerves* are derived from the pelvic plexus of the sympathetic and from the third and the fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distention and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended, it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region which is perceptible to the hand as well as to percussion. In extreme distention it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the serous membrane. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this by some surgeons in performing the operation of suprapubic cystotomy. The rectum is distended by an India-rubber bag, which is introduced into this cavity empty, and then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba, from the symphysis pubis upward, without any great risk of wounding the peritoneum. Other surgeons object to the employment of this bag, as its use is not unattended with risk, and because it causes pressure on the prostatic sinuses and produces congestion of the vessels over the bladder and a good deal of venous hemorrhage.

When distended, the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is also uncovered by peritoneum, and the bladder may here be punctured from the rectum, in the middle line, without risk of wounding the serous membrane.

Surgical Anatomy.—A defect of development in which the bladder is implicated is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red, vascular tumor, on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as *epispadias*. The pelvic bones are also arrested in development (see page 183).

The bladder may be ruptured by violence applied to the abdominal wall when the viscus is distended without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert's suture are resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any

obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these bundles of muscular fibres the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*. The mucous membrane is very loose and lax, except over the trigone, to allow of the distention of the viscus.

Various forms of tumors have been found springing from the wall of the bladder. The innocent tumors are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain. Of the malignant tumors, epithelioma is the most common, but sarcomata are occasionally found in the bladder of children.

Puncture of the bladder may be performed either above the pubes or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been almost completely abandoned.

THE MALE URETHRA.

The urethra in the male extends from the neck of the bladder to the meatus urinarius at the end of the penis. It presents a double curve in the flaccid state of the penis (Fig. 557), but in the erect state of this organ it forms only a single curve, the concavity of which is directed upward. Its length varies from eight to nine inches; and it is divided into three portions, the *prostatic*, *membranous*, and *spongy*, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a more transverse cleft or slit, with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched.

The **Prostatic Portion** is the widest and most dilatable part of the canal. It passes through the prostate gland, from its base to the apex, lying nearer its anterior than its posterior surface. It is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horse-shoe in shape, the convexity being directed forward (Fig. 563), since the direction of the canal is nearly vertical.

Upon the floor of the canal is a narrow longitudinal ridge, the *verumontanum*, or *caput gallinaginis*, formed by an elevation of the mucous membrane and its subjacent tissue. It is eight or nine lines in length, and a line and a half in height; and contains, according to Kobelt, muscular and erectile tissues. When distended, it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the *prostatic sinus*, the floor of which is perforated by numerous apertures, the *orifices of the prostatic ducts* from the lateral lobes of the gland; the ducts of the middle lobe open behind the

FIG. 562.—The male urethra, laid open on its anterior (upper) surface. (Testut.)

verumontanum. At the fore part of the verumontanum, in the middle line, is a depression, the *sinus pocularis* (*vesicula prostatica*); and upon or within its margins are the slit-like openings of the ejaculatory ducts. The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upward and backward in the substance of the prostate behind the middle lobe; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the *uterus masculinus*, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore homologous with the uterus and vagina in the female.

The **Membranous Portion of the Urethra** extends between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meatus), and measures three-quarters of an inch along its upper, and half an inch along its lower, surface, in consequence of the bulb projecting backward beneath it. Its anterior concave surface is placed about an inch below and behind the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis, and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which constitutes the perineum. The membranous portion of the urethra lies between the inferior and superior layers of the triangular ligament. As it pierces the inferior layer, the fibres around the opening are prolonged over the tube. It is also surrounded by the Compressor urethræ muscle.

The **Spongy Portion** is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion of the meatus urinarius. Commencing just below the triangular ligament, it inclines downward for a short distance; it next ascends for about half its length, and then, in the flaccid condition of the penis, it bends suddenly downward. It is narrow, and of uniform size in the body of the penis, measuring about a quarter of an inch in diameter; being dilated behind, within the bulb; and again anteriorly within the glans penis, where it forms the *fossa navicularis*.

The *Bulbous portion* is a name given, in some descriptions of the urethra, to the posterior part of the spongy portion contained within the bulb.

The *meatus urinarius* is the most contracted part of the urethra; it is a vertical slit, about three lines in length, bounded on each side by two small labia.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the *glands of Littre*. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunæ, larger than the rest, is situated in the upper surface of the fossa navicularis, about an inch and a half from the orifice; it is called the *lacuna magna*. Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The urethra is composed of a continuous mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The *mucous coat* forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz. Cowper's glands and the prostate gland—and into the vasa deferentia and vesiculæ seminales through the ejaculatory ducts. In the spongy and membranous portions the mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillæ are found upon it near the orifice, and its epithelial lining is of the columnar variety, excepting near the meatus, where it is squamous.

The *submucous tissue* consists of a vascular erectile layer, outside which is a

layer of unstriped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus spongiosum.

Surgical Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perinæum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perinæum and the history of the accident, will at once point to the nature of the injury.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatability, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore frequently requires slitting. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotrity and introduce that of litholapaxy. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunæ. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal.

THE FEMALE BLADDER AND URETHRA.

The Bladder is situated at the anterior part of the pelvis. It is in relation, *in front*, with the symphysis pubis; *behind*, with the utero-vesical pouch of peritoneum, which separates it from the body of the uterus; its *base* lies in contact with the connective tissue in front of the cervix and upper part of the vagina. *Laterally*, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size.

THE URETHRA.

The Urethra is a narrow membranous canal, about an inch and a half in length, extending from the neck of the bladder to the meatus urinarius. It is placed beneath the symphysis pubis, imbedded in the anterior wall of the vagina; and its direction is obliquely downward and forward, its course being slightly curved, the concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The *muscular coat* is continuous with that of the bladder; it extends the whole length of the tube, and consists of a circular stratum of muscular fibres. In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethræ, as in the male.

A *thin layer of spongy erectile tissue*, containing a plexus of large veins intermixed with bundles of unstriped muscular fibre, lies immediately beneath the mucous coat.

The *mucous coat* is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, resembles the verumontanum in the male urethra. It is lined by laminated epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

The urethra, from not being surrounded by dense resisting structures, as in the male, admits of considerable dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

THE MALE ORGANS OF GENERATION.

THE PROSTATE GLAND.

THE Prostate Gland (*προίστημι, to stand before*) is a pale, firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and around the commencement of the urethra. It is placed in the pelvic cavity, behind the lower part of the symphysis pubis, and above the deep layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut.

FIG. 563.—Transverse section of normal prostate through the middle of the verumontanum, from a subject aged nineteen years. (Taylor.) *a*, Longitudinal sections of ducts leading from the lobules of the prostatic glands; *b*, verumontanum; *c*, sinus pocularis; *d*, urethra; *e*, ejaculatory ducts; *f*, arteries, veins, and venous sinuses in capsule of prostate; *g*, nerve trunks in capsule; *h*, point of origin of fibro-muscular bands encircling urethra; *i*, zone of striated voluntary muscle on superior surface. (Drawn from Erdinger projection apparatus.)

Its *base* is directed upward, and is situated immediately below the neck of the bladder.

Its *apex* is directed downward to the deep layer of the triangular ligament, which it touches.

Its *posterior surface* is flattened, marked by a slight longitudinal furrow, and rests on the second part of the rectum, and is distant about one inch and a half from the anus.

Its *anterior surface* is convex, and placed about three-quarters of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the pubo-prostatic ligaments.

The *lateral surfaces* are prominent, and are covered by the anterior portions

of the Levatores ani muscles, which are, however, separated from the gland by a plexus of veins.

The prostate measures about an inch and a half transversely at the base, an inch in its antero-posterior diameter, and an inch and a quarter in its vertical diameter. Its weight is about four and a half drachms. It is held in position by the anterior ligaments of the bladder (*pubo-prostatic*); by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backward from the os pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the *Levator prostatae*.

The prostate consists of two lateral lobes and a middle lobe.

The *two lateral lobes* are of equal size, separated by a deep notch behind, and by a slight furrow upon the anterior and posterior surfaces of the gland, which indicates the bilobed condition of the organ in some animals.

The third, or *middle lobe*, is a small transverse band, occasionally a rounded or triangular prominence, placed between the two lateral lobes at the posterior part of the organ. It lies immediately beneath the neck of the bladder, behind the commencement of the urethra, and above the ejaculatory ducts, which pass through the gland between its middle and lateral lobes. Its existence is not constant, but it is occasionally found at an early period of life, as well as in adults and in old age.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies along the junction of its anterior with its middle third. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

Structure.—The prostate is immediately enveloped by a thin but firm fibrous capsule, distinct from that derived from the recto-vesical fascia, and separated from it by a plexus of veins. Its substance is of a pale reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the fibrous capsule is a dense layer which forms an investing sheath for the gland; secondly, around the urethra as it lies in the prostate, is another dense layer of circular fibres, continuous above with the internal layer of the muscular coat of the bladder, and below blending with the fibres surrounding the membranous portion of the urethra. Between these two layers strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like toward the apex of the organ.

The *glandular substance* is composed of numerous follicular pouches, opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The follicles are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium lining of both the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the internal pudic, vesical, and hæmorrhoidal. Its *veins* form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and terminate in the internal iliac vein. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of this organ; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys, learn the position, as well as the size and weight, of a calculus in the bladder; and in the operation for its removal, if, as is not unfrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhœa, or tuberculous disease. The gland, being enveloped in a dense unyielding capsule, determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perinæum. In advanced life the prostate becomes considerably enlarged, and projects into the bladder so as to impede the passage of the urine. According to Dr. Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate a pouch is formed at the base of the bladder behind the projection, in which water collects and cannot entirely be expelled. It becomes decomposed and ammoniacal, and leads to cystitis. For this condition "prostatectomy" is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane incised, and the enlarged and projecting middle lobe enucleated.

COWPER'S GLANDS.

Cowper's Glands are two small, rounded, and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the fore part of the membranous portion of the urethra, between the two layers of the triangular ligament. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethræ muscle. Their existence is said to be constant: they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct. The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

THE PENIS.

The **Penis** consists of a root, body, and extremity or *glans penis*.

The *root* is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the *crura*, and to the front of the symphysis pubis by the *suspensory ligament*, a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the upper surface of the root of the penis, where it splits into two portions and blends with the fascial sheath of the organ.

The *extremity* or *glans penis*, presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the orifice of the urethra (*meatus urinarius*). The base of the glans forms a rounded projecting border, the *corona glandis*, and behind the corona is a deep constriction, the *cervix*. Upon both of these parts numerous small sebaceous glands are found, the *glandulæ Tysonii odoriferae*. They secrete a sebaceous matter of very peculiar odor, which probably contains caseine and becomes easily decomposed.

¹ Stieda (*Comptes rendus du XII Congrès International de Médecine*, Moscow, 1897) asserts that Tyson's glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillæ.

The *body of the penis* is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the *dorsum*. The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and its containing no adipose tissue. At the root of the penis the integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the *prepuce*.

The internal layer of the prepuce is attached behind to the cervix, and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The integument covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillæ. At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphé, where it is continuous with the prepuce; this fold is termed the *frænum præputii*.

Structure of the Penis.—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the *corpora cavernosa*, are placed side by side along the upper part of the organ; the third, or *corpus spongiosum*, encloses the urethra and is placed below.

The **Corpora Cavernosa** form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the *crura*, which are two strong tapering fibrous processes firmly connected to the rami of the os pubis and ischium. Each crus commences by a blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum*. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis. A median groove on the upper surface lodges the dorsal vein of the penis, and the groove on the under surface receives the corpus spongiosum. The root of the penis is connected to the symphysis pubis by the suspensory ligament.

Structure.—The corpora cavernosa are surrounded by a strong fibrous envelope, consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, circular in direction, and being proper to each corpus cavernosum. The internal circular fibres of the two corpora cavernosa form, by their junction in the mesial plane, an incomplete partition or septum between the two bodies.

The *septum* between the two corpora cavernosa is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received, *septum pectiniforme*. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. This fibrous investment is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibre, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of the corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculæ*, and consist of white fibrous tissue,

elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves.

The component fibres of which the trabeculæ are composed are larger and stronger round the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue of areolar spaces freely communicating with each other and filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the arteries of the corpora cavernosa and branches from the dorsal artery of the penis, which perforate the fibrous capsule, along the upper surface, especially near the fore part of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculæ. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries*. They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa (Fig. 564).

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and

FIG. 564.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. (Copied from Langer.) 1. a. Capillary network. b. Cavernous spaces. 2. Connection of the arterial twigs (a) with the cavernous spaces.

converge on the dorsum of the organ to form the dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind round the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

The **Corpus Spongiosum** encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa. It commences posteriorly below the superficial layer of the triangular ligament of the urethra, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the *bulb*, and terminates anteriorly in another expansion, the *glans penis*, which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

The *bulb* varies in size in different subjects; it receives a fibrous investment

from the superficial layer of the triangular ligament, and is surrounded by the Accelerator urinæ muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward round the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two lobes, being marked externally by a linear raphé, whilst internally there projects, for a short distance, a thin fibrous septum, which is more distinct in early life.

Structure.—The corpus spongiosum consists of a strong fibrous envelope, enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora cavernosa. The trabeculæ are more delicate, nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstripped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

The *lymphatics of the penis* consist of a superficial and deep set; the former are derived from a dense network on the skin of the glans and prepuce and from the mucous membrane of the urethra, and terminate in the superficial inguinal glands; the latter emerge from the corpora cavernosa and corpus spongiosum, and, passing beneath the pubic arch, join the deep lymphatics of the pelvis.

The *nerves* are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bulb.

Surgical Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the ossa pubis and ischia. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue round the root of the penis, and carried down the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the spongy portion of the urethra below the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perinæum. The remainder of the wound is to be brought together, free drainage being provided for.

THE TESTES AND THEIR COVERINGS (Fig. 565).

The **Testes** are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of foetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by numerous coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum. The coverings of the testes are—the

Skin } Scrotum.
Dartos }

Intercolumnar, or External spermatic fascia.

Cremasteric fascia.

Infundibuliform, or Fascia propria (Internal spermatic fascia).

Tunica vaginalis.

The **Scrotum** is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided on its surface into two lateral portions by a median line, or *raphé*, which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is longer than the right, and corresponds with the greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances: thus under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the integument and the dartos.

The **integument** is very thin, of a brownish color, and generally thrown into folds or *rugæ*. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

The **dartos** is a thin layer of loose reddish tissue, endowed with contractility: it forms the proper tunic of the scrotum, is continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and perinæum,

FIG. 565.—Transverse section through the left side of the scrotum and the left testicle. The sac of the tunica vaginalis represented in a distended condition. (Del  pine.)

and sends inward a distinct septum, *septum scroti*, which divides it into two cavities for the two testes, the septum extending between the raphe and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstriped muscular fibre, but no fat. Its contractility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The **intercolumnar fascia** is a thin membrane derived from the margin of the

pillars of the external abdominal ring, during the descent of the testes in the foetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **cremasteric fascia** consists of scattered bundles of muscular fibres (*Cremaster muscle*) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are continuous with the lower border of the Internal oblique muscle (see page 360).

The **infundibuliform fascia** is a thin membranous layer, which loosely invests the surface of the cord. It is a continuation downward of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior part of the testicle. This connective tissue is continuous above with the subserous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath it, are known collectively as the *fascia propria*.

The **tunica vaginalis** is described with the testis.

Vessels and Nerves.—The *arteries* supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the epigastric. The *veins* follow the course of the corresponding arteries. The *lymphatics* terminate in the inguinal glands. The *nerves* are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

The **Spermatic Cord** extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first between the Internal oblique and upon the fascia transversalis; but nearer the pubes it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

Structure of the Spermatic Cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testicle. These structures are connected together by areolar tissue, and invested by the layers brought down by the testicle in its descent.

The *arteries of the cord* are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastric.

The *spermatic artery*, a branch of the abdominal aorta, escapes from the abdomen at the internal or deep abdominal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back of the tunica albuginea and supply the substance of the testis.

The *cremasteric artery* is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery.

The *artery of the vas deferens*, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery near the testis.

The spermatic veins emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus (*plexus pampiniformis*), which forms the chief mass of the cord: the vessels composing this plexus,

are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the renal vein at a right angle.

The *lymphatic vessels* terminate in the lumbar glands.

The *nerves* are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

Surgical Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of oedema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of epithelioma; this is no doubt due to the rugæ on its surface, which favor the lodgment of dirt, and this, causing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

THE TESTES.

The **Testes** are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the upper extremity being directed forward and a little outward, the lower, backward and a little inward; the anterior convex border looks forward and downward; the posterior or straight border, to which the cord is attached, backward and upward.

The anterior border and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named from its relation to the testis, the epididymis (*ἐπίδυμος*, testis). It consists of a central portion, or *body*; an upper enlarged extremity, the head, or *globus major*; and a lower pointed extremity, the tail, or *globus minor*. The globus major is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border, and between the body and the testicle is a pouch or *cul-de-sac*, named the *digital fossa*. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, are two small pedunculated bodies. One of them is pear-shaped, and attached by its narrow stalk; the other is small and sessile; they are believed to be the remains of the upper extremity of the Müllerian duct, and are termed the *hydatids of Morgagni*; some observers, however, regard the stalked hydatid as being a rudiment of the pronephros. When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

Size and Weight.—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

The testis is invested by three tunics—the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The **Tunica Vaginalis** is the serous covering of the testis. It is a pouch of serous membrane, derived from the peritoneum during the descent of the testis in the fœtus from the abdomen into the scrotum. After its descent that portion of the pouch which extends from the internal ring to near the upper part of the gland becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The *visceral portion of the tunica vaginalis* covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected on to the internal surface of the scrotum.

The *parietal portion of the tunica vaginalis* is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the cavity of the tunica vaginalis.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it

gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1049). Or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.¹

The **Tunica Albuginea** is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testicle, and along its posterior border, where the spermatic-vessels enter the gland. This membrane surrounds the glandular structure of the testicle, and at its posterior border is reflected into the

interior of the gland, forming an incomplete vertical septum, called the *mediastinum testis* (*corpus Highmorianum*).

The *mediastinum testis* extends from the upper, nearly to the lower, extremity

¹ It is recorded that in the post-mortem examination of Sir Astley Cooper this minute canal was found on both sides of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (*Lancet*, 1824, vol. ii., p. 116).

FIG. 566.—The testis *in situ*, the tunica vaginalis having been laid open.

of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa (*trabeculae*) are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. They therefore divide the anterior of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The **Tunica Vasculosa** is the vascular layer of the testis, consisting of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules (*lobuli testis*). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, the *tubuli seminiferi*. The tubes may be separately unravelled by careful dissection under water, and may be seen to commence either by free caecal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300, and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from $\frac{1}{200}$ to $\frac{1}{150}$ of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. Each tube consists of a basement layer, formed of epithelioid cells united edge to edge, outside which are other layers of flattened cells arranged in interrupted laminae, which give to the tube an appearance of striation in cross section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups. Among these cells may be seen the *spermatozoa* in different stages of development. 1. Lining the basement-membrane and forming the outer zone is a layer of cubical cells, with small nuclei; these are known as the *lining cells* or *spermatogonia*. The nucleus of some of them may be seen to be in the process of indirect division (*karyokinesis*), and in consequence of this daughter cells are formed, which constitute the second zone. 2. Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three layers; these are the *intermediate cells* or *spermatocytes*. Most of these cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the *spermatoblasts* or *spermatids*. 3. The third layer of cells therefore consists of the spermatoblasts or spermatids, and each of these, without further subdivision, becomes a *spermatozoon*. They are ill-defined granular masses of protoplasm, of an elongated form, with a nucleus which becomes the head of the future spermatozoon. In addition to these three layers of cells others are seen, which are termed the *supporting cells*, or *cells of Sertoli*. They are elongated and columnar, and project inward from the basement-membrane toward the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermatozoa proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear part of the spermatozoon, which is partly imbedded in the supporting cell, is differentiated to form the head of the spermatozoon, while the cell protoplasm becomes lengthened out to form the middle piece

and tail, the latter projecting into the lumen of the tube. Ultimately the heads are separated and the spermatozoa are set free.

Spermatogenesis.—The stages in the development of the spermatozoa are as follows: The spermatogonia become enlarged to form the spermatocytes, and each spermatocyte subdivides into two cells, and each of these again divides into two spermatids or young spermatozoa, so that the spermatocyte gives origin to four spermatozoa.

The process of spermatogenesis bears a close relation to that of maturation of the ovum. The spermatocyte is equivalent to the immature ovum. It undergoes subdivision, and ultimately gives origin to four spermatozoa, each of which contains, therefore, only one-fourth of the chromatin elements of the nucleus of the spermatocyte. In the process of maturation of the ovum its nucleus divides, one half being extended as the first polar body. The remaining half of the nucleus again subdivides, one half being extended as the second polar body. The portion of the nucleus which is retained to form the female pronucleus of the now matured ovum contains, therefore, only one-fourth of the chromatin elements of the original nucleus, and thus the spermatozoon and the matured ovum, so far as their nuclear elements are concerned, may be regarded as of the same morphological value.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

In the apices of the lobules the tubuli become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about $\frac{1}{30}$ of an inch in diameter, and these, from their straight course, are called *vasa recta*.

The *vasa recta* enter the fibrous tissue of the mediastinum, and pass upward and backward, forming, in their

FIG. 567.—Vertical section of the testicle, to show the arrangement of the ducts.

ascent, a close network of anastomosing tubes, which are merely channels in the fibrous stroma, lined by flattened epithelium, and having no proper walls; this constitutes the *rete testis*. At the upper end of the mediastinum the vessels of the rete testis terminate in from twelve to fifteen or twenty ducts, the *vasa efferentia*: they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged and exceedingly convoluted, and form a series of conical masses, the *coni vasculosi*, which, together, constitute the globus major of the epididymis. Each cone consists of a single convoluted duct from six to eight inches in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and globus minor of the epididymis. When the convolutions of this tube are unravelled, it measures upward of twenty feet in length, and it increases in diameter and thickness as it approaches the vas deferens. The convolutions are held together by fine areolar tissue and by bands of fibrous tissue.

The *vasa recta* are of smaller diameter than the seminal tubes, and have very thin parietes. They, like the channels of the rete testis, are lined by a single layer of flattened epithelium. The *vasa efferentia* and the tube of the epididymis

have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

The **Vas Deferens**, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves round the outer side of the epigastric artery, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the vesicula seminalis. In this situation it becomes enlarged and sacculated, forming the *ampulla*, and then, becoming narrowed at the base of the prostate, unites with the duct of the vesicula seminalis to form the ejaculatory duct. The vas deferens presents a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external or areolar coat. 2. A muscular coat, which in the greater part of the tube consists of two layers of unstripped muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the vas deferens, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane. 3. An internal or mucous coat, which is pale, and arranged in longitudinal folds; its epithelial covering is of the columnar variety.

A long narrow tube, the *vas aberrans of Haller*, is occasionally found connected with the lower part of the canal of the epididymis or with the commencement of the vas deferens. It extends up into the cord for about two or three inches, where it terminates by a blind extremity, which is occasionally bifurcated. Its length varies from an inch and a half to fourteen inches, and sometimes it becomes dilated toward its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis.

Organ of Giralde.—This term is applied to a small collection of convoluted tubules, situated in front of the lower part of the cord or above the globus major of the epididymis. These tubes are lined with columnar ciliated epithelium, and probably represent the remains of a part of the Wolffian body.

Surgical Anatomy.—The testicle frequently requires removal for malignant disease; in tuberculous disease; in cystic disease; in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicles. The operation of castration has also been, during the last few years, performed for enlargement of the prostate; for it has been found that removal of the testicle is followed by very rapid and often considerable diminution in the size of the prostate. The operation is, however, one of severity, and is frequently followed by death in these cases, performed, as it necessarily is, in old men. Reginald Harrison has proposed to substitute for it excision of a portion of the vasa deferentia. The operation of castration is a comparatively simple one. An incision is made into the tunica vaginalis from the external ring to the bottom of the scrotum. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

Spermatozoa.—The spermatozoa are minute, thread-like bodies, which constitute the essential elements of the semen. Each consists of a *head*, a middle piece or *body*, and an elongated filament or *tail*. The head, on surface view, appears oval in shape, but if seen in profile it is narrow and pointed at its free end. It represents

the modified nucleus of the spermatid, and consists chiefly of chromatin, and so stains readily with nuclear reagents; it is covered by a thin cap of protoplasm. The body is a short cylindrical or conical piece, intervening between the head and tail, and is therefore sometimes spoken of as the intermediate segment. The tail is about four times the combined lengths of the head and body; its terminal part is extremely fine, and is named the *end-piece*. Contained within the body and tail is an axial filament, surrounded, except in the end-piece, by a thin layer of protoplasm; this axial filament terminates just below the head in a rounded knob or button. In virtue of their tails, which act as propellers, the spermatozoa, in the fresh condition, are capable of free movement, and if placed in favorable surroundings (*e. g.*, in the female passages) may retain their vitality for some days or even weeks.

VESICULÆ SEMINALES.

The **Seminal Vesicles** are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal

FIG. 568.—Base of the bladder, with the vasa deferentia and vesiculæ seminales.

in form, the broad end being directed backward and the narrow end forward toward the prostate. They measure about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. Their *upper surface* is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. Their *under surface* rests upon the rectum, from which they are separated by the recto-vesical fascia. Their *posterior extremities* diverge from each other. Their *anterior extremities* are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicula runs the enlarged and convoluted vas deferens. The inner border of the vesiculæ and the corresponding vas deferens form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum.

Each vesicula consists of a single tube, coiled upon itself and giving off several irregular cæcal diverticula, the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in

a *cul-de-sac* ; its anterior extremity becomes constricted into a narrow straight duct, which joins with the corresponding vas deferens, and forms the ejaculatory duct.

The **ejaculatory ducts**, two in number, one on each side, are formed by the junction of the ducts of the vesiculæ seminales with the vasa deferentia. Each duct is about three-quarters of an inch in length ; it commences at the base of the prostate, and runs forward and downward between its middle and lateral lobes, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to or just within the margins of the sinus. The ducts diminish in size and also converge toward their termination.

Structure.—The vesiculæ seminales are composed of three coats : an *external* or *areolar* ; a *middle* or *muscular coat*, which is thinner than in the vas deferens, arranged in two layers, an outer, longitudinal, and inner, circular ; an *internal* or *mucous coat*, which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are : an *outer fibrous layer*, which is almost entirely lost after their entrance into the prostate ; a *layer of muscular fibres*, consisting of an outer thin circular and an inner longitudinal layer ; and the *mucous membrane*.

Vessels and Nerves.—The *arteries* supplying the vesiculæ seminales are derived from the middle and inferior vesical and middle hæmorrhoidal. The *veins* and *lymphatics* accompany the arteries. The *nerves* are derived from the pelvic plexus.

Surgical Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculous disease of the testicle, and should always be examined from the rectum before coming to a decision with regard to castration in this affection.

THE FEMALE ORGANS OF GENERATION.

EXTERNAL ORGANS.

THE External Organs of Generation in the Female are: the mons Veneris, the labia majora and minora, the clitoris, the meatus urinarius, and the orifice of

FIG. 569.—The vulva. External female organs of generation.

the vagina. The term “vulva” or “pudendum,” as generally applied, includes all these parts.

The **Mons Veneris** is the rounded eminence in front of the pubic symphysis, formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

The **Labia Majora** are two prominent longitudinal cutaneous folds extending downward from the mons Veneris to the anterior boundary of the perinæum, and

enclosing the common urino-sexual opening. Each labium has two surfaces, an outer, which is pigmented and covered with strong, crisp hairs; and an inner, which is smooth and is beset with large sebaceous follicles and is continuous with the genito-urinary mucous tract; between the two there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the *anterior commissure*. Posteriorly they are not really joined, but appear to become lost in the neighboring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the posterior commissure or posterior boundary of the vulval orifice. The

FIG. 570.—Vertical median section of the female pelvis.

interval between the posterior commissure and the anus, about an inch to an inch and a quarter in length, constitutes the perinæum. The *fourchette* is the anterior edge of the perineum, and between it and the hymen is a depression, the *fossa navicularis*. The labia correspond to the scrotum in the male.

The *Labia Minora*, or *Nymphæ*, are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downward, outward, and backward for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost. Anteriorly, the two labia minora meet and form the *frænum of the clitoris*. The *prepuce* of the clitoris, passing backward on each side, is inserted, as it were, into the labium minora, but is not actually a part of them. The nymphæ are really modified skin. Their internal surfaces have numerous sebaceous follicles.

The *Clitoris* is an erectile structure analogous to the corpora cavernosa of the penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It is connected to the rami of the os pubis

and ischium on each side by a crus; the body is short and concealed beneath the labia; the free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. It is provided, like the penis, with a suspensory ligament, and with two small muscles, the *Erectores clitoridis*, which are inserted into the crura of the clitoris. The clitoris consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

Between the clitoris and the entrance of the vagina is a triangular smooth surface, bounded on each side by the nymphæ; this is the *vestibule*.

The orifice of the urethra (*meatus urinarius*) is situated at the back part of the vestibule, about an inch below the clitoris and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the meatus urinarius is the orifice of the vagina, more or less closed in the virgin by a membranous fold, the *hymen*.

The *Hymen* varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly: sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called "imperforate hymen." Occasionally it is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After parturition the small rounded elevations known as the *carunculæ myrtiformes* are found as the remains of the hymen.

Glands of Bartholin.—On each side of the commencement of the vagina, and behind the hymen, is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper's gland in the male. It is called the *gland of Bartholin*. Each gland opens by means of a long single duct immediately external to the hymen, in the angle or groove between it and the nymphæ.

Bulbi Vestibuli.—Extending from the clitoris, along either side of the vestibule, and lying a little behind the nymphæ, are two large oblong masses, about an inch in length, consisting of a plexus of veins enclosed in a thin layer of fibrous membrane. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes: they are termed by Kobelt the *bulbi vestibuli*, and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front: it is called by Kobelt the *pars intermedia*, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb.

INTERNAL ORGANS.

The **Internal Organs of Generation** are—the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments.

The **Vagina** extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches along its anterior wall, and three and a half inches along its posterior wall. It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus.

Relations.—Its *anterior surface* is in relation with the base of the bladder and with the urethra. Its *posterior surface* is connected for the lower three-fourths of its extent to the anterior wall of the rectum, the upper fourth being separated from that tube by the recto-vaginal pouch of peritoneum, or pouch of Douglas, between the vagina and rectum. Its sides are enclosed between the Levatores ani muscles.

Structure.—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

The *mucous membrane* is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the *columns of the vagina*, and numerous transverse ridges or rugæ, extending outward from the raphé on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The sub-mucous tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The *muscular coat* consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi which pass from the one layer to the other. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the *sphincter vaginae* (see page 375).

External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The *erectile tissue* consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; imbedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

THE UTERUS.

The **Uterus** is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fœtus, and becoming the principal agent in its expulsion at the time of parturition.

In the *virgin state* it is pear-shaped, flattened from before backward, and situated in the cavity of the pelvis between the bladder and the rectum; it is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below. Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The uterus measures about three inches in length, two in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts: (1) the *body*, with its upper broad extremity, the *fundus*; and (2) the *cervix*, or *neck*, which is partly above the vagina and partly in the vagina. The fundus is placed on a line below the level of the brim of the pelvis, and its direction varies with the condition of the bladder.

The division between the body and cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal, called the *internal os*.

The *body* gradually narrows from the fundus to the neck. Its anterior surface is flattened, covered by peritoneum, which becomes separated from it at its union with the cervix, in order to form the utero-vesical pouch, which lies between the uterus and bladder. Its *posterior surface* is convex transversely, covered by peritoneum throughout, and separated from the rectum by some convolutions of the intestine. Its *lateral margins* are concave, and give attachment to the Fallopian tube above, the round ligament below and in front of this, and the ligament of the ovary behind both of these structures.

The *cervix* is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina, which extends upward a greater distance behind than in front.

The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it. The vaginal portion is the rounded lower end projecting into

FIG. 571.—Douglas's pouch. (From a preparation in the Museum of the Royal College of Surgeons of England.)

the vagina. On its surface is a small aperture, the *os uteri*, generally circular in shape, but sometimes oval or almost linear. The margin of the opening is, in the absence of past parturition or disease, quite smooth.

Ligaments.—The ligaments of the uterus are eight in number: one anterior; one posterior; two lateral or broad; two sacro-uterine,—all these being formed of peritoneum—and, lastly, two round ligaments.

The *anterior ligament* (vesico-uterine) is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body.

The *posterior ligament* (recto-uterine) passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch called *Douglas's pouch* (Fig. 571), the boundaries of which are,

that portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of the division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, the internal orifice (*ostium internum*), which leads into the cavity of the cervix.

The **cavity of the cervix** is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name *arbor vitæ uterina* applied to it. These folds usually become very indistinct after the first labor.

Structure.—The uterus is composed of three coats: an external serous coat, a middle or muscular, and an internal mucous coat.

The *serous coat* is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriated muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. In the impregnated state the muscular tissue becomes more prominently developed, and is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary: some passing at each side into the broad ligament, and others running backward from the cervix into the sacro-uterine ligaments.

The middle layer of fibres, which is thickest, presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most blood-vessels.

The internal or deep layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal os these circular fibres form a distinct sphincter.

The *mucous membrane* is thin, smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the *body* of the uterus it is smooth, soft, of a pale red color lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is unprovided with any submucosa, but is intimately connected with the innermost layer of the muscular coat, which is regarded as the *muscularis mucosæ*. In structure its *corium* differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like *uterine glands*, which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged, elongated, presenting a contorted or waved appearance toward their closed extrem-

ities, which reaches into the muscularis, and may be single or bifid. They consist of a delicate membrane, lined by an epithelium, which becomes ciliated toward the orifices. The changes which take place in the mucous membrane of the impregnated uterus are more fully dealt with in the section on Embryology.

In the *cervix* the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphé, presenting an appearance which has received the name of *arbor vitæ*. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the *ovula Nabothi*. The mucous membrane covering the lower half of the cervical canal

FIG. 573.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.

Vessels and Nerves.—The *arteries of the uterus* are the uterine, from the internal iliac, and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being, as shown by Sir John Williams, circular. The *veins* are of large size, and correspond with the arteries. In the impregnated uterus these vessels form the *uterine sinuses*, consisting of the lining membrane of the veins adhering to the walls of the canal channelled through the substance of the uterus. They terminate in the uterine plexuses. The *lymphatics* of the body terminate in the lumbar glands, those of the cervix in the pelvic glands. The *nerves* are derived from the inferior hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the fœtus the uterus is contained in the abdominal cavity, projecting beyond the brim of the pelvis. The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from eight to ten drachms. It has descended into the pelvis, the fundus being just below the level of the brim of this cavity. The arbor vitæ is distinct, and extends to the upper part of the cavity of the organ.

The position of the uterus in the adult is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is directed forward, and is at the same time bent on itself at the junction of the body and cervix, so that the body lies upon the bladder. As the latter fills the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be directed backward toward the sacrum.

During menstruation the organ is enlarged and more vascular, its surfaces rounder; the os externum is rounded, its labia swollen, and the lining membrane of the body thickened, softer, and of a darker color. According to Sir J. Williams, at each recurrence of menstruation a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands imbedded in the muscle being left. At the cessation of menstruation by a proliferation of the remaining structures a fresh mucous membrane is formed.

During pregnancy the uterus becomes enormously enlarged, and in the ninth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle and partly to development of new fibres.

After parturition the uterus nearly regains its usual size, weighing about an ounce and a half; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are tortuous, and its muscular layers are more defined.

In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The ostium internum and, occasionally, the vaginal orifice often become obliterated, and its labia almost entirely disappear.

Surgical Anatomy.—The uterus may require removal in cases of malignant disease or for fibroid tumors. Carcinoma is the most common form of malignant disease of the uterus, though cases of sarcoma do occur. It may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous covering of the vaginal surface of the cervix. The columnar form may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section. The former operation is the better of the two, and is attended by a much smaller death-rate. Vaginal hysterectomy is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum. The cervix is then seized with a volsellum and pulled down as far as possible and the mucous membrane of the vagina incised around the cervix and as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. A pair of dressing forceps are then pushed through into Douglas's pouch and opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesico-uterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues off the anterior uterine wall. When the vesico-uterine pouch has been opened and the opening dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas's pouch and an aneurism needle, armed with a long silk ligature, is inserted into the vesico-uterine pouch, and is pushed through the broad ligament about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery (Fig. 573), enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably further down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins, and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. This canal is then sponged out and lightly dressed with gauze; no sutures being used. The gauze may be removed at the end of the second day. In squamous epithelioma, amputation of the cervix is all that is necessary in those cases where the disease is recognized before it has invaded the walls of the vagina or the neighboring broad ligaments. The operation consists in removing a wedge-shaped piece of the uterus, including

the cervix, through the vagina and attaching the cut surfaces of the stump to the anterior and posterior vaginal walls, so as to prevent retraction. In the treatment of uterine fibroids which require operative interference, removal of the whole of the uterus together with the tumors through an abdominal incision gives the most satisfactory results; for, if the tumor is large, its size acts as a barrier to its safe delivery through the pelvis and genital passages. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a similar manner to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the two first ligatures have been tied, and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is cut across. The uterus is now turned forward and the peritoneum at the bottom of Douglas's pouch incised transversely, and the posterior wall of the vagina cut across until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is not sutured.

APPENDAGES OF THE UTERUS.

The **appendages** of the uterus are the Fallopian tubes, the ovaries and their ligaments, and the round ligaments. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

THE FALLOPIAN TUBES.

The **Fallopian Tubes**, or **Oviducts**, convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches in length; and is described as consisting of three portions: (1) the *isthmus*, or inner constricted third; (2) the *ampulla*, or outer dilated portion, which curves over the ovary; and (3) the

FIG. 574.—Uterine appendages, seen from behind. (Henle.)

infundibulum with its *ostium abdominale*, surrounded by fimbriæ, one of which is attached to the ovary, the *fimbria ovarica*. The general direction of the Fallopian tube is outward, backward and downward. The uterine opening is minute, and will admit only a fine bristle; the abdominal opening is somewhat larger. In connection with the fimbriæ of the Fallopian tube or with the broad ligament close

to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the *hydatids of Morgagni*.

Structure.—The Fallopian tube consists of three coats—serous, muscular, and mucous.

The *external* or *serous coat* is peritoneal.

The *middle* or *muscular coat* consists of an external longitudinal and an internal circular layer of muscular fibres continuous with those of the uterus.

The *internal* or *mucous coat* is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the outer, larger part of the tube, or ampulla, are much more extensive than in the narrow canal of the isthmus. The lining epithelium is columnar ciliated. This form of epithelium is also found on the inner surface of the fimbriae, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

THE OVARIES.

The **ovaries** (*testes muliebres*, Galen) are analogous to the testes in the male. They are oval-shaped bodies of an elongated form, flattened from above downward, situated one on each side of the uterus, in the posterior layer of the broad ligament behind and below the Fallopian tubes. Each ovary is connected by its anterior straight margin to the broad ligament; by its lower extremity to the uterus by a proper ligament, the *ligament of the ovary*; and by its upper end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria; its mesial and lateral surfaces and posterior convex border are free. The ovaries are of a grayish-pink color, and present either a smooth or puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weigh from one to two drachms.

FIG. 575.—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen: thus the right ovary has been raised above the Fallopian tube, and the fimbriated extremities of the tubes have been turned upward and outward. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The exact position of the ovary has been the subject of considerable difference of opinion, and writers differ much as to what is to be regarded as the normal position. The fact appears to be that it is differently placed in different individuals. Hasse has described it as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its

long axis is antero-posterior. Kölliker asserts that the truth lies between these two views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulo-pelvic ligament (page 1030). When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbriæ pass upward on to the ovary and closely embrace it.

Waldeyer¹ states, as the result of the examination of fifty female subjects, ranging from early childhood to advanced age, that the ovary "lies on the lateral pelvic wall and vertically when the woman takes the erect posture." Its *tubal* extremity is near the external iliac vein; its uterine end is directed downward, while the Fallopian tube overlies it so as to cover it on its medial face entirely or nearly so. Its convex margin looks downward and backward toward the pelvic cavity and rectum, while its straight margin or hilum lies laterally on the pelvic wall attached to the mesosalpinx. He also finds that it lies in a distinct but shallow groove (*fossa ovarii*) limited above by the hypogastric artery and below by the ureter, in such a manner that the ureter lies along the convex margin of the ovary, and the hypogastric artery passes near the hilum or straight margin.

Structure.—The ovary consists of a number of Graafian vesicles imbedded in the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

Serous Covering.—Though the investing membrane of the ovary is derived from the peritoneum, it differs essentially from that structure, inasmuch as its epithelium consists of a single layer of columnar cells, instead of the flattened endothelial cells of other parts of the membrane; this has been termed the *germinal epithelium of Waldeyer*, and gives to the surface of the ovary a dull gray aspect instead of the shining smoothness of serous membranes generally.

Stroma.—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriated muscle-cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Kölliker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the *tunica albuginea*, but is nothing more than a condensed layer of the stroma of the ovary.

Graafian Vesicles.—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the *Graafian vesicles* or ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles of uniform size, about $\frac{1}{100}$ of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the *cortical layer*. They are especially numerous in the ovary of the young child. After puberty

¹ *Journal of Anatomy and Physiology*, vol. xxxii.

and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also "corpora lutea," the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum other large and more mature Graafian vesicles are found imbedded in the ovarian stroma.

FIG. 576.—Section of the ovary. (After Schron.) 1. Outer covering. 1'. Attached border. 2. Central stroma. 3. Peripheral stroma. 4. Blood-vessels. 5. Graafian follicles in their earliest stage. 6, 7, 8. More advanced follicles. 9. An almost mature follicle. 9'. Follicle from which the ovum has escaped. 10. Corpus luteum.

FIG. 577.—Section of the Graafian vesicle. (After Von Baer.)

These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the *medullary substance* (*zona vasculosa*, Waldeyer). This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The larger *Graafian follicles* consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named *ovicapsule*, which is lined by a layer of nucleated cells, called the *membrana granulosa*. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the *membrana granulosa* are collected into a mass which projects into the cavity of the vesicle. This is termed the *discus proligerus*, and in this the ovum is imbedded.¹

The ova are formed from the germinal epithelium on the surface of the ovary. This becomes thickened, and in it are seen some cells which are larger and more rounded than the rest; these are termed the *primordial ova*. The germinal epithelium grows downward in the form of tubes or columns, termed the *egg tubes* of Pflüger, into the ovarian stroma, which grows outward between the tubes, and ultimately cuts them off from the germinal epithelium. These tubes are further subdivided into rounded *nests* or groups, each containing a primordial ovum which undergoes further development and growth while the surrounding cells of the nest form the epithelium of the Graafian follicle.

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vessels contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear. At puberty the ovaries enlarge, and become more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst: the ovum and fluid contents of the vesicles are

¹ For a description of the ovum, see section on Embryology.

liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube.¹

In the foetus the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

Lying above the ovary in the broad ligament between it and the Fallopian tube is the *organ of Rosenmüller*, called also the *parovarium* or *epoöphoron*. This is the remnant of a foetal structure, the development of which is described in the section on Embryology. In the adult it consists of a few closed convoluted tubes, lined with epithelium, which converge toward the ovary at one end and at the other are united by a longitudinal tube, which is the homologue of the *duct of Gärtner* in the cow. This duct terminates in a bulbous enlargement. The parovarium is connected at the uterine extremity with the remains of the Wolffian duct. A few scattered rudimentary tubules, best seen in the child, are situated in the broad ligament between the parovarium and the uterus. These constitute the *paroöphoron of Waldeyer*.

The **ligament of the ovary** is a rounded cord, which extends from each superior angle of the uterus to the inner extremity of the ovary; it consists of fibrous tissue and a few muscular fibres derived from the uterus.

The **Round Ligaments** are two rounded cords, between four and five inches in length, situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing on each side at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labia majora, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplicature of peritoneum, which in the foetus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which precedes the descent of the testis.

Vessels and Nerves.—The *arteries of the ovaries and Fallopian tubes* are the ovarian from the aorta. They enter the attached border, or hilum, of the ovary. The *veins* follow the course of the arteries; they form a plexus near the ovary, the *pampiniform plexus*. The *nerves* are derived from the inferior hypogastric or pelvic plexus, and from the ovarian plexus, the Fallopian tube receiving a branch from one of the uterine nerves.

THE MAMMARY GLANDS.

The **mammæ**, or breasts, secrete the milk, and are accessory glands of the generative system. They exist in the male as well as in the female; but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences situated toward the lateral aspect of the pectoral region, corresponding to the intervals between the third and sixth or seventh ribs, and extending from the side of the sternum to the axilla. Their weight and dimensions differ at different periods of life and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. Their base is nearly circular, flattened or slightly concave, and has its long diameter directed upward and outward toward the axilla; they are separated from the Pectoral

¹ This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.

muscles by a layer of fascia. The outer surface of the mamma is **convex**, and presents, just below the centre, a small conical prominence, the nipple (*mammilla*). The surface of the nipple is dark-colored and surrounded by an areola having a colored tint. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, which increases as pregnancy advances, becoming in some cases of a dark-brown or even black color. This color diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the color of the areola are of importance in forming a conclusion in a case of suspected first pregnancy.

FIG. 578.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)

The **nipple** is a cylindrical or conical eminence capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with papillæ, and it is perforated by numerous orifices, the apertures of the lactiferous ducts. Near the base of the nipple and upon the surface of the areoli are numerous sebaceous glands, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance, which serves as a protection to the integument of the nipple during the act of sucking. The nipple consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base, some few fibres radiating from base to apex.

Structure.—The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, circular in form, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. It consists of numerous lobes, and these are composed of lobules connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts: these ducts, uniting, form larger ducts, which terminate in a single canal, corresponding with one of the chief subdivisions of the gland. The number of excretory ducts

varies from fifteen to twenty : they are termed the *tubuli lactiferi*, or *galactophori*. They converge toward the areola, beneath which they form dilatations, or *ampullæ*, which serve as reservoirs for the milk, and at the base of the nipple become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres ; muscular fibres are entirely absent ; their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk as *colostrum-corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with a spherical nucleus, lining the limiting *membrana propria*. These cells during the state of activity of the gland are capable of forming, in their interior, oil-globules, which are then ejected into the lumen of the alveolus and constitute the milk-globules.

The *fibrous tissue* invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The *fatty tissue* surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and Nerves.—The *arteries* supplying the *mammæ* are derived from the thoracic branches of the axillary, the intercostals, and internal mammary. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus*. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The *lymphatics*, for the most part, run along the lower border of the *Pectoralis major* to the axillary glands ; some few, from the inner side of the breast, perforate the intercostal spaces and empty themselves into the anterior mediastinal glands. The *nerves* are derived from the anterior and lateral cutaneous nerves of the *thorax*.

THE SURGICAL ANATOMY OF HERNIA.

Dissection (Fig. 217).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated through an aperture made at the umbilicus. An incision should be made along the middle line from a little below the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen.—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The *superficial layer (fascia of Camper)*, is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perinæum. In the female this fascia is continued into the labia majora.

The *hypogastric branch of the ilio-hypogastric nerve* perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The *ilio-inguinal nerve* escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The *superficial epigastric artery* arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The *superficial circumflex iliac artery*, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The *superficial external pudic (superior) artery* arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are

usually much larger than the arteries; they terminate in the internal saphenous vein.

The *superficial inguinal lymphatic glands* are placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament; which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous

FIG. 579.—Inguinal hernia. Superficial dissection.

vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *deep layer of the superficial fascia (fascia of Scarpa)* is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the base of the triangular ligament of the urethra. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends (see page 1014).

The Aponeurosis of the External Oblique Muscle.—This is a thin but strong

membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called *Poupart's ligament*. The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called *Gimbernat's ligament*. From the point of attachment of the latter to the pectineal line a few fibres pass upward and inward, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous band, which is called the *triangular fascia of the abdomen*.

The External or Superficial Abdominal Ring.—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the *external abdominal ring*. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the *intercolumnar*, which pass across the upper angle of the ring, so as to increase its strength; and on either side, by the margins of the opening in the aponeurosis, which are called the *columns* or *pillars of the ring*.

The *external pillar*, which at the same time is *inferior* from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The *internal* or *superior pillar* is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the great frequency of inguinal hernia in men.

The *intercolumnar fibres* are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they are connected to the outer third of Poupart's ligament, and are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the *intercolumnar fascia*. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the *external spermatic fascia*. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring, and then, if the limb is extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downward and outward: great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (Fig. 580). The mode of insertion of Poupart's and Gimbernat's ligaments into the os pubis should also be examined.

Poupart's ligament, or the crural arch, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming

FIG. 580.—Inguinal hernia. Dissection showing the Internal oblique and Cremaster.

Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction; its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Gimbernat's Ligament (Fig. 588) is that portion of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the femoral sheath, forming the inner boundary of the crural ring (see Fig. 588). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **triangular fascia of the abdomen** is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar

of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

The **Internal oblique muscle** has been previously described (page 360). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. This tendon is inserted immediately behind the inguinal canal and external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The **Cremaster** is a thin muscular layer composed of a number of fasciculi which arise from the middle of Poupart's ligament at the inner side of the Internal oblique, being connected with that muscle and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremasterica*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of fœtal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal herniæ. No such muscle exist in the female, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous incisions, and reflected inward on to the sheath of the Rectus (Fig. 581). The deep circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.

The **Transversalis muscle** has been previously described (page 362). The part which is now exposed is partly muscular and partly tendinous in structure; it arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and the pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Trans-

versalis. Between the lower border of this muscle and Poupart's ligament a space is left in which is seen the transversalis fascia.

The **inguinal** or **spermatic canal** contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the inguinal canal, and terminates below at the external or superficial ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the transversalis fascia with Poupart's ligament. That form of hernia in which the intestine follows the course of the spermatic cord along the inguinal canal is called *oblique inguinal hernia*.

The **transversalis fascia** is a thin aponeurotic membrane which lies between

FIG. 581.—Inguinal hernia. Dissection showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.

the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments: external to the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the femoral sheath. The spermatic cord

in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on the structures forming the infundibuliform fascia.

The internal or deep abdominal ring is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, its long diameter being directed upward and downward; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference, a thin, funnel-shaped membrane, the *infundibuliform fascia*, is continued round the cord and testis, enclosing them in a distinct pouch. When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform fascia constitutes one of its coverings.

The Subperitoneal Areolar Tissue.—Between the transversalis fascia and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness and loaded with adipose tissue. Opposite the internal ring it is continued round the surface of the cord, forming a loose sheath for it.

The *deep epigastric artery* arises from the external iliac artery a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upward pierces the transversalis fascia and enters the sheath of the Rectus muscle by passing over the semilunar fold of Douglas. Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring and beneath the commencement of the spermatic cord. At its commencement it is crossed by the vas deferens in the male and by the round ligament in the female.

The peritoneum, corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost. This is the remains of the pouch of peritoneum which, in the foetus, precedes the cord and testis into the scrotum, the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance, but occasionally it may be followed, as a fine cord, as far as the upper end of the tunica vaginalis. Sometimes the tube of peritoneum is closed only at intervals and presents a sacculated appearance, or a single pouch may extend along the whole length of the cord, which may be closed above, or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female foetus the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes it remains pervious even in advanced life.

In order to understand the relation of the peritoneum to inguinal hernia, it is necessary to view the anterior abdominal wall from its internal aspect, when it will be seen as shown in Fig. 582. Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five vertical folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus. One of these is situated in the median line, and is caused by the urachus, the remnant of the allantois: it extends from the summit of the bladder to the umbilicus. The fold of peritoneum covering it is known as the *plica urachi*. On either side of this is a prominent band, caused by the obliterated hypogastric artery, which extends from the side of the bladder

obliquely upward and inward to the umbilicus. This is covered by a fold of peritoneum, which is known as the *plica hypogastrica*. To either side of these three cords is the deep epigastric artery, which ascends obliquely upward and inward from a point midway between the symphysis pubis and the anterior superior spine of the ilium to the semilunar fold of Douglas, in front of which it disappears. It is covered by a fold of peritoneum, which is known as the *plica epigastrica*. Between these raised folds are depressions of the peritoneum, constituting so-called fossæ. The most internal, between the plica urachi and the plica hypogastrica, is known as the *internal inguinal fossa* (fovea supravesicalis). The middle one is situated between the plica hypogastrica and the plica epigastrica, and is termed the *middle inguinal fossa* (fovea inguinalis mesialis). The external one is external to

FIG. 582.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)

the plica epigastrica, and is known as the *external inguinal fossa* (fovea inguinalis lateralis). Occasionally the deep epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line, and the two external fossæ are merged into one. In the usual condition of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the plica epigastrica are the two internal fossæ, and through either of these a direct hernia may descend, as will be explained in the sequel (page 1052). The whole of this space, that is to say, the space between the deep epigastric artery, the margin of the Rectus and Poupart's ligament, is commonly known as *Hesselbach's triangle*. These three depressions or fossæ are situated above the level of Poupart's ligament, and in addition to them is another below the ligament, corresponding to the position of the femoral ring, and into which a femoral hernia descends.

INGUINAL HERNIA.

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—external or oblique, and internal or direct.

External or oblique inguinal hernia, the more frequent of the two, takes the same course as the spermatic cord. It is called *external* from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

Oblique Inguinal Hernia.

In oblique inguinal hernia the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum, which forms the hernial

FIG. 583.—Oblique inguinal hernia, showing its various coverings. (From a preparation in the Museum of the Royal College of Surgeons.)

sac (Fig. 584, A). As it enters the inguinal canal it receives an investment from the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia. In passing along the inguinal canal it displaces upward the arched fibres of the Transversalis and Internal oblique muscles, and is surrounded by the fibres of the Cremaster. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from

the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

FIG. 584.—Varieties of oblique inguinal hernia.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar

fascia, Cremaster muscle, infundibuliform fascia, subserous areolar tissue, and peritoneum.

This form of hernia lies in front of the vessels of the spermatic cord and seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis.

The *seat of stricture* in oblique inguinal hernia is either at the external ring, in the inguinal canal, caused by the fibres of the Internal oblique or Transversalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the intestine passes along the inguinal canal and escapes from the external ring into the scrotum, it is called *complete oblique inguinal* or *scrotal hernia*. If the intestine does not escape from the external ring, but is retained in the inguinal canal, it is called *incomplete inguinal hernia*, or *bubonocoele*. In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is preceded by a pouch of peritoneum, which about the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at two points—viz. at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

Congenital Hernia (Fig. 584, B).—Where the pouch of peritoneum which precedes the cord and testis in its descent remains patent throughout and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

Infantile and Encysted Hernia.—Where the pouch of peritoneum is occluded at the internal ring only, and remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the *infantile* form (Fig. 584, c) the bowel, pressing upon the septum and the peritoneum in its immediate neighborhood, causes it to yield and form a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and its own sac. In the *encysted* form (Fig. 584, d) pressure in the same position—namely, at the occluded spot in the pouch—causes the septum to yield and form a sac which projects *into* and not *behind* the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and its own sac.

Hernia into the Funicular Process (Fig. 584, E).—Where the pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has

formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

Direct Inguinal Hernia.

In direct inguinal hernia the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.

At the lower part of the abdominal wall is a triangular space (*Hesselbach's triangle*), bounded externally by the deep epigastric artery, internally by the margin of the Rectus muscle, below by Poupart's ligament (Fig. 582). The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric the projection of these arteries toward the cavity of the abdomen produces two fossæ in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, it divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall, viz., an external one, on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery (see page 1051). In such a case a hernia may distend and push out the peritoneum forming the bottom of either fossa. When the hernia distends and pushes out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia. These fossæ are the *inguinal fossæ*.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be

the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the transversalis fascia, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The *seat of stricture* in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not unfrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward.¹

If the hernial protrusion passes into the inguinal canal, but does not escape from the external abdominal ring, it forms what is called *incomplete direct hernia*. This form of hernia is usually of small size, and in corpulent persons very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

FEMORAL HERNIA.

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon its back; a block is first placed under the pelvis, the thigh everted, and the knee slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart's ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh. These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The **superficial fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected out-

¹ In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward: the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, it would stand an equal chance of injury if the case was one of oblique inguinal hernia.

ward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The *internal or long saphenous vein* ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives at the saphenous opening the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins.

The *superficial external pudic artery* (superior) arises from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male and the labium in the female, anastomosing with branches of the internal pudic.

The *superficial epigastric artery* arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the

FIG. 585.—Femoral hernia. Superficial dissection.

External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The *superficial circumflex iliac artery*, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel

with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The Superficial Veins.—The veins accompanying these superficial arteries are usually much larger than the arteries: they terminate in the internal or long saphenous vein at the saphenous opening.

The *superficial inguinal lymphatic glands*, placed immediately beneath the integument, are of large size and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The *ilio-inguinal nerve* arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric: in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The *crural branch of the genito-crural nerve* passes along the inner margin of the Psoas muscle, beneath Poupart's ligament, into the thigh, entering the sheath of the femoral vessels, and lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The *deep layer of the superficial fascia* is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart's ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.

The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The **Fascia Lata** has been already described with the muscles of the front of the thigh (page 419). At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the *saphenous opening*. In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The *iliac portion* is all that part of the fascia lata on the outer side of the

saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart's ligament; and to the pectineal line in conjunction with Gimbernat's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the outer boundary or falciform process or superior cornu of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached the cribriform fascia, and below it is continuous with the pubic portion of the fascia lata.

The *pubic portion of the fascia lata* is situated at the inner side of the saphenous opening: at the lower margin of this aperture it is continuous with the iliac portion: traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture

FIG. 586.—Femoral hernia, showing fascia lata and saphenous opening.

consequently exists between the two, through which the internal saphenous joins the femoral vein.

The **Saphenous Opening** is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner part of the front of the thigh, below Poupart's ligament, and is directed obliquely downward and outward.

Its *outer margin* is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced

upward, it will be seen to form a curved elongated process, the *falciform process* or *superior cornu*, which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward: this is the inferior cornu of the saphenous opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The *inner boundary of the opening* is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb

FIG. 587.—Femoral hernia. Iliac portion of fascia lata removed, and sheath of femoral vessels and femoral canal exposed.

and inverting it: hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart's ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart's ligament (Fig. 587).

Poupart's Ligament, or the **Crural Arch**, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of

the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the whole of the space included between the crural arch and innominate bone is filled in by the parts which descend from the abdomen into the thigh (Fig. 588). The outer half of the space is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half of the space is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath, which is occupied merely by a little loose areolar tissue, a few lymphatic vessels,

FIG. 588.—Structures which pass beneath the crural arch.

and occasionally by a small lymphatic gland; this is the femoral ring, through which the gut descends in femoral hernia.

Gimbernat's Ligament (Figs. 588, 589) is that part of the aponeurosis of the External oblique muscle which is reflected backward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its *base*, or outer margin, is concave, thin, and sharp, and lies in contact with the femoral sheath. Its *apex* corresponds to the spine of the os pubis. Its *posterior margin* is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its *anterior margin* is continuous with Poupart's ligament.

Femoral Sheath.—The femoral or crural sheath is a continuation downward of the fasciæ that line the abdomen, the transversalis fascia passing down in front of the femoral vessels, and the iliac fascia descending behind them; these fasciæ are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the femoral or crural canal. The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed, the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic

FIG. 589.—Hernia. The relations of the femoral and internal abdominal rings, seen from within the abdomen. Right side.

gland: this is the femoral or crural canal, through which the intestine descends in femoral hernia.

Deep Crural Arch.—Passing across the front of the femoral sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres called the *deep crural arch*. It is apparently a thickening of the transversalis fascia, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

The **crural canal** is the narrow interval between the femoral vein and the inner wall of the femoral sheath. It exists as a distinct canal only when the sheath has

been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from Gimbernat's ligament to the upper part of the saphenous opening.

Its *anterior wall* is very narrow, and formed by a continuation downward of the transversalis fascia, under Poupart's ligament, covered by the falciform process of the fascia lata.

Its *posterior wall* is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its *outer wall* is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its *inner wall* is formed by the junction of the processes of the transversalis and iliac fasciæ, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the *femoral* or *crural ring*, closed by the septum crurale; and a lower one, the *saphenous opening*, closed by the cribriform fascia.

The **femoral** or **crural ring** (Fig. 589) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of Parts around the Ring.—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The *femoral vein* lies on the outer side of the ring.

The *deep epigastric artery* in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The *communicating branch* between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind. It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The *obturator artery*, when it arises by a common trunk with the deep epigastric, which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In most cases it descends on the inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (see Fig. 314, page 565, fig. A). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen: it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (see Fig. 314, page 565, fig. B).

Septum Crurale.—The femoral ring is closed by a layer of condensed areolar tissue called, by J. Cloquet, the *septum crurale*. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave, and supports a small lymphatic gland by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral

canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral canal and its orifices are rendered tense from the traction on these parts by Poupart's ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The *subperitoneal areolar tissue* is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the small interval (crural ring) on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart's ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. It has here no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall: hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms what is called the *hernial sac*; it receives an investment from the subserous areolar tissue and from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the tumor is consequently directed forward, pushing before it the cribriform fascia, and then curves upward on to the falciform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribriform fascia, superficial fascia, and integument.¹

¹ Sir Astley Cooper has described an investment for femoral hernia, under the name of "*fascia propria*," lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text "*subserous areolar tissue*," the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.

Varieties of Femoral Hernia.—If the intestine descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, it is called *incomplete femoral hernia*. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be, from without inward, integument, superficial fascia, falciform process of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernial tumor protrudes through the saphenous opening and directs itself forward and upward, it forms a *complete femoral hernia*. Occasionally the hernial sac descends on the iliac side of the femoral vessels or in front of these vessels, or even sometimes behind them.

The *seat of stricture of a femoral hernia* varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat's ligament, or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in a direction upward and inward, and the extent necessary in the majority of cases is about two or three lines. By these means all vessels or other structures of importance in relation with the neck of the hernial sac will be avoided.

SURGICAL ANATOMY OF THE PERINÆUM.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 590, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The **Perinæum** corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the os pubis and ischium, the tuberosities of the ischium, and great sacro-sciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thighs. A line drawn transversely between the anterior part of the tuberosity of the ischium, on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the *perinæum proper* or *genito-urinary region*. The posterior portion contains the termination of the rectum, and is called the *ischio-rectal* or *anal region*.

ISCHIO-RECTAL REGION.

The **ischio-rectal region** contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium: this is called the *ischio-rectal fossa*.

The **ischio-rectal region** presents in the middle line the *aperture of the anus*: around this orifice the integument is thrown into numerous folds, which are obliterated on distension of the intestine. The integument is of a dark color, continuous with the mucous membrane of the rectum, and provided with numerous follicles, which occasionally inflame and suppurate, and may be mistaken for fistulæ. The veins around the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish color, covered partly by mucous membrane and partly by the integument. These tumors constitute the disease called *external piles*.

Dissection (Fig. 590).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it round the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

The **superficial fascia** is exposed on the removal of the skin: it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three branches of the perforating cutaneous nerve; these turn round the inferior border of the Gluteus maximus and are distributed to the integument around the anus.

In this region, and connected with the lower end of the rectum, are four

muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Levator ani.

These muscles have been already described (see page 368).

The ischio-rectal fossa is situated between the end of the rectum and the tuberosity of the ischium. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its apex, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, *internally*, by the Sphincter ani, Levator ani, and Coccygeus muscles; *externally*, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; *in front*, it is limited by the line of junction of the superficial fascia with the base of the triangular ligament; and *behind*, by the margin of the Gluteus maximus and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and the two divisions of the nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath (canal of Alcock) formed by the obturator fascia, the pudic nerve lying below the artery and the dorsal nerve of the penis above it (Fig. 315). Crossing the space transversely, about its centre are the inferior hemorrhoidal vessels and nerves, which are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome hemorrhage when divided in the operation of lithotomy or in that for fistula in ano. At the back part of this space, near the coccyx, may be seen a branch of the fourth sacral nerve, and at the fore part of the space the superficial perineal vessels and nerves can be seen for a short distance.

THE PERINÆUM PROPER IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the anterior parts of the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perinæum is subdivided by the median raphe into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perinæum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the *raphe*, continuous in front with the raphe of the scrotum.

Upon removing the skin and superficial structures from this region, in the manner shown in Fig. 590, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the *deep layer of the superficial fascia* or *fascia of Colles*. It has already

been described (page 370). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversus perinæi muscles to join the base of the triangular ligament.

It is between this layer of fascia and the triangular ligament of the urethra that extravasation of urine most frequently takes place in cases of rupture of the urethra. The triangular ligament of the urethra (see page 373) is attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, but these two layers are continuous with each other around the Transversi perinæi muscles: it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the triangular ligament, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and then on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed, a space is exposed, between this fascia and the triangular ligament, in which are contained the superficial perineal vessels and nerves and some of the muscles connected with the penis and urethra, viz., in the middle line, the Accelerator urinæ; on each side, the Erector penis; and behind, the transversus perinæi; together with the crura of the corpora cavernosa and the bulb of the corpus spongiosum. Here also is seen the *central tendinous point of the perineum*. This is a fibrous point in the middle line of the perineum between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached, viz.,

FIG. 590.—Dissection of perinæum and ischio-rectal region.

the External sphincter ani, the Accelerator urinæ, and the two Transversi perinæi muscles; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The Accelerator urinæ, the Erector penis, and the Transversus perinæi muscles have been already described (page 371). They form a triangular space, bounded, internally, by the Accelerator urinæ; externally, by the Erector penis; and behind, by the Transversus perinæi. The floor of this space is formed by the triangular ligament of the urethra; and running from behind forward in it are the superficial perineal vessels and nerves, and the transverse perineal artery coursing along the posterior boundary of the space, on the Transversus perinæi muscle.

The Accelerator urinæ and Erector penis should now be removed, when the triangular ligament of the urethra will be exposed, stretching across the front of the outlet of the pelvis. The urethra is seen perforating its centre, just behind the bulb; and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

The **Triangular Ligament**, which has already been described (see page 373), consists of two layers, the inferior superficial layer of which is now exposed.

It is united to the superior or deep layer behind, but is separated in front by a subfascial space in which are contained certain structures.

The *inferior layer of the triangular ligament* consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side of the urethral opening by the ducts of Cowper's glands and by the arteries of the bulb; in front, and external to this, by the artery of the corpus cavernosum, immediately before this vessel enters the crus penis. Near its apex the ligament is perforated by the termination of the pudic artery and by the dorsal nerve of the penis. The *crura penis* are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberosities, and passing forward and inward, joining to form the body of the penis. In the middle line the bulb and corpus spongiosum are exposed by the removal of the Accelerator urinæ muscle.

FIG. 591.—The superficial muscles and vessels of the perinæum.

If the superficial layer of the deep perineal fascia is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the ligament: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

The *superior layer of the triangular ligament*, or *deep perineal fascia*, is derived from the obturator fascia, and is continuous with it along the pubic arch. Behind, it joins with the superficial layer of the triangular ligament, and is continuous with the anal fascia. Above it is the prostate gland, supported by the anterior fibres of the Levator ani, which act as a sling for the gland and form the Levator prostatae muscle. The superior layer of the triangular ligament is continuous

round the anterior free edge of this muscle with the recto-vesical layer covering the prostate gland. The superior layer of the triangular ligament is perforated by the urethra. Between the two layers of the triangular ligament are situated the membranous part of the urethra, enveloped by the *Compressor urethræ* muscle; the ducts of Cowper's glands; the arteries to the bulb; the pudic vessels and the dorsal nerve of the penis. The membranous part of the urethra is about three-quarters of an inch in length, and passes downward and forward behind the symphysis pubis, from which it is distant about an inch. It is the narrowest part of the tube, and is enveloped, as has already been stated, by the *Compressor urethræ* muscle.

The *Compressor urethræ* has already been described (page 374). In addition to this muscle and immediately beneath it *circular muscular fibres* surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

FIG. 592.—Deep perineal fascia. On the left side the anterior layer has been removed.

The **pudic vessels and dorsal nerve of the penis** are placed along the inner margin of the pubic arch (pages 565 and 793).

The **artery of the bulb** passes transversely inward, from the internal pudic along the base of the triangular ligament, between its two layers, accompanied by a branch of the pudic nerve (page 567). If the deep layer of the triangular ligament is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani is brought fully into view. This muscle, with the triangular ligament in front and the Coccygeus and Pyliformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (page 369).

Position of the Viscera at the Outlet of the Pelvis.—Divide the central tendinous point of the perinæum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculæ seminales, and the vasa deferentia will be exposed.

The **Prostate Gland** is a pale, firm, glandular body which is placed immediately below the neck of the bladder, around the commencement of the urethra. It is placed in the pelvic cavity, behind the lower part of the symphysis pubis, above the deep layer of the triangular ligament, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed upward toward the neck of the bladder. Its apex is directed downward to the deeper layer of the triangular ligament, which it touches.

Its posterior surface is smooth, marked by a slight longitudinal furrow, and rests on the second part of the rectum, to which it is connected by areolar tissue. Its anterior surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy.

FIG. 593.—A view of the position of the viscera at the outlet of the pelvis.

Above the prostate a small triangular portion of the bladder is seen, bounded, in front and below, by the prostate gland; above, by the recto-vesical fold of the peritoneum; on each side, by the vesicula seminalis and the vas deferens. It is separated from direct contact with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts: this portion of the bladder is, consequently, occasionally selected for the performance of the operation of tapping the bladder.

Surgical Anatomy.—The student should consider the position of the various parts in reference to the lateral operation of lithotomy. This operation is performed on the left side of the perinæum, as it is most convenient for the right hand of the operator. A grooved staff having been

introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (*i. e.* in an ordinary adult perinæum about an inch and a half in front of the anus) a little on the left side of the raphe, and carried obliquely backward and outward to midway between the anus and tuberosity of the ischium. The incision divides the integument and superficial fascia, the inferior hæmorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering it are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger of the left hand passed along the staff into the bladder. The position of the stone having been ascertained, the staff is to be withdrawn, and the forceps is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may be notched before the forceps is introduced: the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious undulating movements.

Parts Divided in the Operation.—The various structures divided in this operation are as follows: the integument, superficial fascia, inferior hæmorrhoidal vessels and nerves, and probably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinæ, the Transversus perinæi muscle and artery, the triangular ligament, the anterior fibres of the Levator ani, part of the Compressor urethræ, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perinæum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum; nor too far externally, otherwise the pudic artery may be implicated as it ascends along the inner border of the pubic arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, only the anterior part of the prostate is divided, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder *before* the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perinæum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable to be wounded in the operation for lithotomy in its passage forward to the bulb. The accessory pudic may be divided near the posterior border of the prostate gland, if this is completely cut across; and the prostatic veins, especially in people advanced in life, are of large size, and give rise, when divided, to troublesome hæmorrhage.

THE FEMALE PERINÆUM.

The female perinæum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The superficial fascia, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is like it attached to the ischio-pubic ramus, and in front is continued forward through the labia majora to the inguinal region. It is of less extent than the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perinæum, which have already been described (page 374), are exposed. The Sphincter vaginae, corresponding to the Accelerator urinæ in the male, consists of an attenuated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphe, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect, and the Transversus perinæi is similar to the muscle of the same name in the male.

The triangular ligament of the urethra is not strongly marked as in the male. It transmits the urethra and the tube of the vagina.

The **Compressor Urethræ** (*Transversus perinæi profundus*) corresponds with the Compressor urethræ in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perinæum.

The distribution of the internal pudic artery is the same as in the male (see page 567), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the *bulbi vestibuli* and *partes intermediales* (see page 1027).

The **perineal body** fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and

FIG. 594.—A transverse section of the pelvis, showing the pelvic fascia from behind.

vagina on what is called the “perinæum.” Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are situated the muscles belonging to the external organs of generation. Through its centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perinæum are inserted.

THE PELVIC FASCIA.

The **Pelvic fascia** (Fig. 595) is a thin membrane which lines the whole of the cavity of the pelvis and is continuous over the back part of the ilio-pectineal line with the iliac fossa. It is attached to the brim of the pelvis, for a short dis-

tance, at the side of the cavity, and to the inner surface of the bone round the attachment of the Obturator internus. At the posterior border of this muscle it is continued backward as a very thin membrane in front of the Pyriformis muscle and sacral nerves to the front of the sacrum. In front it follows the attachment of the Obturator internus to the bone, arches beneath the obturator vessels, completing the orifice of the obturator canal, and at the front of the pelvis is attached to the lower part of the symphysis pubis. At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium is a thickened whitish band, termed the *white line*; this marks the attachment of the Levator ani muscle to the pelvic fascia, and corresponds to its point of division into two layers, the *obturator* and *recto-vesical*.

The obturator fascia descends and covers the Obturator internus muscle. It is a direct continuation of the parietal pelvic fascia below the white line above mentioned, and is attached to the pelvic arch, the ischial tuberosities, and to the margin of the great sacro-sciatic ligaments. This fascia forms a canal for the pudic

FIG. 595.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciae.

vessels and nerve in their passage forward to the perinæum, and gives off a thin membrane which covers the perineal aspect of the Levator ani muscle, called the *ischio-rectal (anal) fossa*. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the deep layer of the triangular ligament.

The *recto-vesical fascia (visceral layer of the pelvic fascia)* descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued, on each side of the middle line, to the upper surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued

on to the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the vesiculæ seminales, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected round the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia, the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the *ischio-rectal* or *anal fascia*. In the female the vagina perforates the recto-vesical fascia, and receives a prolongation from it.

GENERAL ANATOMY OR HISTOLOGY.

THE ANIMAL CELL (Fig. 596).

ALL the tissues and organs of which the body is composed were originally developed from a microscopic body (the *ovum*), consisting of a soft gelatinous granular material enclosed in a membrane, and containing a vesicle, or small spherical body, inside which are one or more solid spots. This may be regarded as a perfect cell. Moreover, all the solid tissues can be shown to consist largely of similar bodies or cells, differing, it is true, in external form, but essentially similar to an ovum.

In the higher organisms all such cells may be defined as “nucleated masses of protoplasm of microscopic size.” The two essentials, therefore, of an animal

FIG. 596.—Diagram of a cell. (Modified from Wilson.)

cell in the higher organisms are, the presence of a soft gelatinous granular material, similar to that found in the ovum, and which is usually styled *protoplasm*; and a small spherical body imbedded in it, and termed a *nucleus*; ¹ the remaining constituents of the ovum—viz., its limiting membrane and the solid spot contained in the nucleus, called the *nucleolus*—are not considered essential to the cell, and in fact many cells exist without them.

Protoplasm (*cytoplasm*) is a material probably of variable constitution, but yielding to the chemist on its disintegration bodies chiefly of proteid nature. Lecithin and cholesterin are constantly found in it, as well as inorganic salts, chief among which are the phosphates and chlorides of the alkali metals and calcium. It is of a semifluid, viscid consistence, and appears either as a hyaline substance, homogeneous and clear, or else it exhibits a granular appearance. This gran-

¹ In certain lower forms of life masses of protoplasm without a nucleus have been described by Huxley and others as cells.

ular appearance, under a high power of the microscope, is seen to be due to the fact that protoplasm consists of a network or honeycombed reticulum, containing in its meshes a homogeneous substance. The former is known as *spongioplasm*, the latter as *hyaloplasm*. The granular appearance is often caused by the knots of the network being mistaken for granules; but, in addition to this, protoplasm often contains true granules, some of which are proteid in nature and probably essential constituents; others are fat- or pigment-granules, and are regarded as adventitious material taken in from without. The size and shape of the meshes of the spongioplasm vary in different cells and in different parts of the same cell. In many fixed cells, *e. g.*, epithelial cells, the external layer becomes denser than the rest, and often altered by the deposition in it of some chemical substance, so as to constitute a membrane which encloses the rest of the protoplasm and forms the *cell-wall*. The relative amount of spongioplasm and hyaloplasm varies in different cells; the latter preponderating in the young cell and the former increasing in amount, at the expense of the hyaloplasm, as the cell grows.

The most striking characteristics of protoplasm are its vital properties of *motion* and *nutrition*. By motion is meant the property which protoplasm has of changing its shape and position by some intrinsic power, which enables it to thrust out from its main body an irregular process, into which the whole of the protoplasmic substance is gradually drawn, so that the mass comes to occupy a new position. This, on account of its resemblance to the movements observed in the *Amœba* or *Proteus* animalcule, has been termed "amœboid movement." Ciliary movement, or the vibration of hair-like processes from the surface of any structure, may also be regarded as a variety of the motion with which protoplasm is endowed.

Nutrition is the power which protoplasm has of attracting to itself the materials necessary for its growth and maintenance from surrounding matter. When any foreign particle comes in contact with the protoplasmic substance, it becomes incorporated in it by being enwrapped by one or more processes projected from the parent mass which enclose it. When thus taken up, it may remain in the substance of the protoplasm for some time without change, or may be again extruded.

The *nucleus* is a minute body, imbedded in the protoplasm, and usually of a spherical or oval form, its size having little relation to the size of the cell. It is surrounded by a well-defined wall, the *nuclear membrane*, which encloses the nuclear contents. These are known as the *nuclear substance* (nuclear matrix), which is composed of a homogeneous material and a stroma or network. The former is probably of the same nature as the hyaloplasm of the cell, but the latter, which forms also the wall of the nucleus, differs from the spongioplasm of the cell-substance. It is sometimes known as the *chromoplasm* or *intranuclear network*, and consists of a network of fibres or filaments arranged in a reticular manner. These filaments stain very readily with certain dyes; they are therefore named *chromatin*; while the interstitial substance does not stain readily, and is hence called *achromatin*. In some resting nuclei, *i. e.*, nuclei which are not undergoing subdivision, the nuclear filaments do not form a network, but present the appearance of a convoluted skein, similar to that found in a nucleus about to undergo division, and which will be immediately described.

Within the nuclear matrix are one or more highly refracting bodies, termed *nucleoli*, connected with the nuclear membrane by the nuclear filaments. They are regarded as being of two kinds. Some are mere local condensations of the chromoplasm; these are irregular in shape and are termed *pseudo-nucleoli*; others are distinct bodies differing from the pseudo-nucleoli both in nature and chemical composition; they may be termed *true nucleoli*, and are usually found in resting cells.

The nuclear substance differs chemically from ordinary protoplasm in containing *nuclein*, in its power of resisting the action of acids and alkalis, in its imbibing more intensely the stain of carmine, hæmatoxylin, etc., and in its remaining unstained by some reagents which color ordinary protoplasm.

Recent investigations tend to show that most living cells contain, in addition to their protoplasm and nucleus, a minute particle which, on account of the power it appears to possess of attracting the surrounding protoplasmic granules, is termed the *attraction-particle* or *centrosome*; it usually lies near the nucleus. The spherical arrangement of fibrillar rows of granules surrounding the central particle is termed the *attraction-sphere* or *centrosphere*. These spheres are usually double, and are connected by a spindle-shaped system of delicate fibrils (*achromatic spindle*). They are best seen in young cells which are about to undergo the process of division, a process believed to commence in these bodies.

The process of reproduction of cells is usually described as being brought about by *indirect* or by *direct division*. *Indirect division* or *karyokinesis* (*karyomitosi*s) has been observed in all the tissues—generative cells, epithelial tissue, connective tissue, muscular tissue, and nerve-tissue—and probably it will ultimately be shown that the division of cells always takes place in this way, and that the process of reproduction of cells by direct division is, as is believed by some observers, merely a sort of imperfect or abnormal karyokinesis.

The process of indirect cell-division is characterized by a series of complex changes in the nucleus, leading to its subdivision; this being followed by cleavage of the cell-protoplasm. Starting with the nucleus in the quiescent or *resting* stage, these changes may be briefly grouped under the four following phases:

1. *Prophase*.—The nuclear network of chromatin-filaments assumes the form of a twisted *skein* or *spirem*, while the nuclear membrane and nucleolus disappear. The convoluted skein of chromatin divides into a definite number of V-shaped loops or *chromosomes*. Coincident with or preceding these changes the centrosome, or attraction-particle, which usually lies by the side of the nucleus, undergoes subdivision, and the two resulting centrosomes, each surrounded by a centrosphere, are seen to be connected by a spindle of delicate achromatic fibres, the *achromatic spindle*. These centrosomes move away from each other—one toward each extremity of the nucleus—and the fibrils of the achromatic spindle are correspondingly lengthened. The centrosomes are now situated one at either extremity or pole of the elongated spindle, and each is surrounded by a centrosphere, from which fibrils radiate into the investing protoplasm. A line encircling the spindle midway between its poles is named the *equator*, and around this the V-shaped chromosomes arrange themselves in the form of a star, thus constituting the *mother star* or *monaster*.

2. *Metaphase*.—Each V-shaped chromosome now undergoes longitudinal cleavage into two equal halves or *daughter chromosomes*, the cleavage commencing at the apex of the V and extending along its divergent limbs. The daughter chromosomes, thus separated, travel in opposite directions along the fibrils of the achromatic spindle toward the centrosomes, around which they group themselves, and thus two star-like figures are formed, one at either pole of the achromatic spindle. This is termed the *diaster*.

3. *Anaphase*.—The V-shaped daughter chromosomes now assume the form of a *skein* or *spirem*, and eventually form the network of chromatin which is characteristic of the resting nucleus. The nuclear membrane and nucleolus are also differentiated during this phase. The cell-protoplasm begins to appear constricted around the equator of the achromatic spindle, where double rows of granules are also sometimes seen. The constriction deepens and the original cell gradually becomes divided.

4. *Telophase*.—In this stage the cell is completely divided into two new cells, each with its own nucleus, centrosome, and centrosphere, which assume the ordinary positions occupied by such structures in the resting stage.

In the case of prickly-cells the subdivision of the cell is incomplete; here the achromatic spindle-threads appear to persist and bridge across the intercellular spaces, constituting the prickles.

The series of diagrams (Fig. 597), by Professor S. Delépine, is intended to explain the formation of some of the most important changes observed in nuclei

FIG. 597.—Karyokinesis; or indirect cell-division. A. Resting nucleus. B. Skein or spirem, close. C. Skein or spirem, open. D. Mother star, monaster. E. Metaphase. F. Daughter stars or diaster. G. of cells during karyokinesis (mitosis); it is based chiefly on the work of Flemming, Strasburger, E. van Beneden, Rabl, O'Hertwig, Hennequy, etc. A. *Resting nucleus*. Nucleolus and nuclear membrane visible. A centrosome is represented near the nucleus. B and C. *Skein or spirem*. Chromatic filaments much convoluted. Evidence of longitudinal splitting begins to be distinct in several parts. The centrosome has divided; the nuclear membrane is becoming indistinct. The two centrosomes are widely separated, and the space between them is occupied by the achromatic spindle. (Two arrows indicate the position which the centrosomes will ultimately occupy; during their passage to these points the achromatic spindle seems to be within the nucleus.) The nuclear membrane has disappeared. D. *Mother star, monaster*. The nuclear segments (chromosomes) resulting from the breaking-up of the chromatic filament into fragments of nearly equal length have moved toward the equator of the spindle, where they now form an equatorial plate. These segments are all split longitudinally. E. *Metaphase*. One half of each chromosome moves toward one pole and the other half toward the other pole, being guided toward the centrosomes by the achromatic filaments. F. *Daughter stars or diaster*. G. *Daughter skeins or dispirem*, beginning to form. Segments in the form of thick loops not closely packed. H. *Daughter skeins or dispirem*, formed. Segments more closely packed and less distinct, owing to the formation of anastomoses. I. *Resting daughter nuclei*. Cell completely divided into two, but bridges remain between them in the region previously occupied by the achromatic filaments, these being specially distinct in certain cells, e. g., prickly-cells. The nucleus has a distinct nuclear membrane and a nucleolus.

In the reproduction of cells by *direct* division the process is brought about either by segmentation or by gemmation. In reproduction by *segmentation* or *fission* the nucleus becomes constricted in its centre, assuming an hour-glass shape, and then divides into two. This leads to a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. These daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. In reproduction by *gemmation* a budding-off or separation of a portion of the nucleus and parent-cell takes place, and, becoming separated, forms a new organism.

The *cell-wall*, which is not an essential constituent, and in fact is often absent, is merely the external layer of the protoplasm, firmer than the rest of the cell, and often thickened by the deposit in it of certain chemical substances. It forms a flexible, transparent, finely striated membrane, sometimes furnished with minute pores, so as to be permeable to fluids.

THE NUTRITIVE FLUIDS.

The *circulating fluids* of the body, which subserve its nutrition, are the blood, the lymph, and the chyle.

THE BLOOD.

The blood is an opaque, rather viscid fluid, of a bright-red or scarlet color when it flows from the arteries, of a dark-red or purple color when it flows from the veins. It is salt to the taste, and has a peculiar faint odor and an alkaline reaction. Its specific gravity is about 1.060, and its temperature is generally about 100° F., though varying slightly in different parts of the body.

General Composition of the Blood.—Blood consists of a faintly yellow fluid, the *plasma* or *liquor sanguinis*, in which are suspended numerous minute particles, the *blood-corpuscles*, the majority of which are colored and give to the blood its red tint. If a drop of blood is placed in a thin layer on a glass slide and examined under the microscope, a number of these corpuscles will be seen immersed in the clear fluid plasma.

The *Blood-corpuscles* are chiefly of two kinds: (1) colored corpuscles or

erythrocytes, (2) colorless corpuscles or leucocytes. A third variety, the blood-platelets, are of subsidiary importance.

1. **Colored or red corpuscles** (*erythrocytes*), when examined under the microscope, are seen to be circular disks, biconcave in profile. They have no nuclei,

but in consequence of their biconcave shape present, according to the alteration of focus under an ordinary high power, a central part, sometimes bright, sometimes dark, which has the appearance of a nucleus (Fig. 598, *a*). It is to their aggregation that the blood owes its red hue, although when examined by transmitted light their color appears to be only a faint reddish yellow. Their size varies slightly even in the same drop of blood; but it may be stated that their ordinary diameter is about $\frac{1}{3200}$ of an inch, while their thickness is about $\frac{1}{12000}$ of an inch or nearly one-quarter of

FIG. 598.—Human red blood-corpuscles. Highly magnified. *a*. Seen from the surface. *b*. Seen in profile and forming rouleaux. *c*. Rendered spherical by water. *d*. Rendered crenate by salt solution.

their diameter. Besides these there are found, especially in disease (*e. g.*, anæmic conditions), certain smaller corpuscles of about one-half or one-third of the size just indicated; these are termed *microcytes*, and are very scarce in human blood. The number of red corpuscles in the blood is enormous; between 4,000,000 and 5,000,000 are contained in a cubic millimetre. Power states that the red corpuscles of an adult would present an aggregate surface of about 3000 square yards. Each corpuscle consists of a colorless elastic spongework or stroma, condensed at the periphery to form an investing membrane, and uniformly diffused throughout this are the colored fluid contents. The stroma is composed mainly of *nucleo-proteid* and of the fatty substances, *lecithin* and *cholesterin*, while the colored material consists chiefly of the respiratory proteid, *hæmoglobin*, which contains a proportion of iron in addition to the ordinary proteid elements. This proteid has a great affinity for oxygen, and when removed from the body crystallizes readily under certain circumstances. It is very soluble in water, the addition of which to a drop of blood speedily dissolves out the hæmoglobin from the corpuscles.

If the web of a frog's foot is spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the wall of the vessel. Doubtless the same is the case in the human body; but when the blood is drawn and examined on a slide without reagents, the corpuscles often collect into heaps like rouleaux of coins (Fig. 598, *b*). It has been suggested that this phenomenon may be explained by alteration in surface tension.

During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves to some extent to the size of the vessel. They are, however, highly elastic, and speedily recover their shape when the pressure is removed. They are soon influenced by the medium in which they are placed, and by the specific gravity of the medium. In water they swell up, lose their shape, and become globular (Fig. 598, *c*). Subsequently the hæmoglobin becomes dissolved out, and the envelope can be barely distinguished as a faint, circular outline. Solutions of salt or sugar, denser than the plasma, give them a stellate or crenated appearance (Fig. 598, *d*); but the usual shape may be restored by diluting the solution to the same specific gravity as the plasma. The crenated outline may be produced as the first effect of the passage of an electric shock; subsequently, if sufficiently strong, the shock ruptures the envelope. A solution

of salt or sugar of the same specific gravity as the plasma, merely separates the blood-corpuscles mechanically without changing their shape.

The **colorless corpuscles** (*leucocytes*) are of various sizes, some no larger, others even smaller, than the red corpuscles. In human blood, however, the majority are rather larger than the red corpuscles, and measure about $\frac{1}{2000}$ to $\frac{1}{2500}$ of an inch in diameter. On the average from 10,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

They consist of minute masses of nucleated protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm and by the staining reactions of these granules when present (Fig. 599). (1) The most numerous and important are spherical in shape, and are characterized by a nucleus, which often consists of two or three parts (multipartite) connected together by fine threads of chromatin. The protoplasm is clear, and contains a number of very fine granules, which stain with acid dyes, as eosin (Fig. 599, 3). (2) A second variety comprises about 2.4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of a coarsely granular protoplasm, the granules being highly refractile and grouped round a single nucleus of horseshoe shape (Fig. 599, 1). These granules stain deeply with eosin, and the cells are therefore often termed *eosinophile corpuscles*.

(3) A leucocyte characterized by the presence of a trilobed nucleus, and having in its protoplasm fine granules which stain with basic dyes, such as methylene-blue, is found in small numbers (Fig. 599, 5). (4) The fourth variety is called the *hyaline cell* (Fig. 599, 4). This is usually about the same size as that of the eosinophile cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules, but is not quite transparent, having the appearance of ground glass. (5) The fifth kind of colorless corpuscle is designated the *lymphocyte* (Fig. 599, 2), because it is identical with the lymphoid cell derived from the lymphatic glands, the spleen, tonsil, and thymus. It is the smallest of the leucocytes, and consists chiefly of a spheroidal nucleus with very little surrounding protoplasm of a homogeneous nature; it is regarded as the immature form of the hyaline cell. The fourth and fifth varieties together constitute from 20 to 30 per cent. of the colorless cells, but of these two varieties the lymphocytes are by far the more numerous.

The white corpuscles are very various in shape in living blood (Fig. 600), because many of them have the power of constantly changing their form by protruding finger-shaped or filamentous processes of their own substance, by which

FIG. 599.—Varieties of leucocytes found in human blood. 1. Eosinophile cell with coarse granules and horseshoe-shaped nucleus. 2. Lymphocyte. 3. Polynuclear or finely granular cell. 4. Hyaline cell, showing nucleus with chromatin threads and two centrosomes in clear protoplasm. 5. Finely granular leucocyte; the nucleus is lobed, the granules stain with basic dyes, such as methylene-blue.

FIG. 600.—Human colorless blood-corpuscle, showing its successive changes of outline within ten minutes when kept moist on a warm stage. (Schofield.)

they move, and may take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and then shifts the rest of the body into it. In the same way when any granule or particle comes in its way it wraps a pseudopodium round it, and then withdrawing it, lodges the particle in its own substance. By means of these amoeboid properties the cells have the power of wandering or emigrating from the blood-

vessels by penetrating their walls and thus finding their way into the extra-vascular spaces. A chemical investigation of the protoplasm of the leucocytes shows the presence of nucleo-proteid and of a globulin. The occurrence of small amounts of fat and glycogen may also be demonstrated.

The **Blood-platelets** are discoid or irregularly shaped, colorless, refractile bodies, much smaller than the red cells. Considerable discussion has arisen as to their significance. In spite of the fact that they have been observed in the blood-vessels during life, there is, at present, a tendency to regard them as products of disintegration of the white cells, or as precipitates, possibly of nucleo-proteid, and not as living elements of the blood.

Origin of the Blood-corpuscles.—In the embryo the red corpuscles are developed from mesoblastic cells in the vascular area of the blastoderm. These cells unite with one another to form a network, their nuclei multiply in number, and around some of the nuclei an aggregation of colored protoplasm takes place. After a time the network becomes hollowed out by an accumulation of fluid, and forms capillary blood-vessels, and in the fluid those nuclei which are surrounded by colored protoplasm float as the first red blood-cells.¹ The embryonic corpuscles are thus nucleated, and, further, they have the power of amoeboid movement. These cells disappear in later embryonic life, to be replaced by smaller non-nucleated corpuscles, having all the characters of the adult erythrocyte, which, according to Schäfer, are formed within certain cells of the connective tissue. Small globules of reddish coloring-matter appear in the protoplasm of these cells, and these eventually becoming larger, more uniform in size and disk-shaped, float in a cavity which results from the coalescence of numerous vacuoles. The cells becoming more hollowed join with neighboring cells to form new blood-vessels, and these become connected with previously existing vessels. In post-embryonic life the important source of the red corpuscles is the red marrow in the ends of the long bones and especially in the ribs and sternum. Here are found special, nucleated, colored cells, termed *erythroblasts*, which are probably direct descendants of the nucleated, embryonic red cells. These erythroblasts by atrophy and disappearance of their nuclei (or, as some observers maintain, by their extrusion) and by assumption of the biconcave form are transformed into the adult red corpuscle. Of the white corpuscles of the blood, the lymphocytes are derived from lymphatic tissue generally, and from the lymphatic glands especially, and enter the blood by way of the lymph-stream; the hyaline cells probably develop from the lymphocytes, while the eosinophile cells are believed to originate mainly in the bone-marrow and possibly also in the connective tissues.

The **Plasma** or **Liquor Sanguinis**, the fluid portion of the blood, has a yellowish tint, is alkaline in reaction, and of a specific gravity of 1.028. It contains in solution about 10 per cent. of solids, of which four-fifths are proteid in nature; the remainder being salts, chiefly chlorides, phosphates, and sulphates of the alkali metals; carbohydrates, chiefly sugar; fats and soaps, cholesterin, urea, and other nitrogenous extractives. The proteids are three in number, *serum albumen*, *serum globulin*, and *fibrinogen*. Fibrinogen is a body of the globulin class, but differs from serum globulin in several respects. It is the substance from which the *fibrin*, which plays so important a part in the clotting of the blood, is derived.

Coagulation of the Blood.—When blood is drawn from the body and allowed to stand, it solidifies in the course of a very few minutes into a jelly-like mass or “clot,” which has the same appearance and volume as the fluid blood and, like it, looks quite uniform. Soon, however, drops of a transparent yellowish fluid, the “serum,” begin to ooze from the surface of the mass and to collect around it. Coincidentally the clot begins to contract, so that in the course of about twenty-four hours, having become considerably smaller and firmer than the first formed jelly-like mass, it floats in a quantity of yellowish serum. The clotting of the blood is due to the formation of a fine meshwork of the insoluble material, *fibrin*, which

¹ Recent observations tend to show that the endothelial lining of the vessels and the blood-corpuscles are of hypoblastic origin.

entangles and encloses the blood-corpuscles. It is supposed that when blood is drawn a nucleo-proteid, termed *prothrombin*, appears in the plasma, probably as the result of disintegration of some of the white cells and perhaps also the blood-platelets. This substance interacts with soluble lime salts in the blood, and a fresh body, *thrombin* or *fibrin-ferment*, is the result. The thrombin then acts on the fibrinogen in solution in the plasma, converting it into insoluble fibrin, while at the same time a very small amount of a new proteid of the globulin type passes into solution.

Fibrin may be obtained, practically free from corpuscles, by whipping the blood, after it has been withdrawn from the body, with a bundle of twigs, to which the fibrin adheres as it is formed. By various means the clotting of the blood may be retarded, so that the plasma may be obtained free from corpuscles; from this plasma there may be derived fibrin and serum, without the cellular elements. Fibrin thus obtained is a white or buff-colored stringy substance, and when observed in the course of formation, under the microscope, shows a meshwork of fine fibrils. After exposure to the air for some time it becomes hard, dry, brown, and brittle. It is one of the class of coagulated proteids, insoluble in hot or cold water, saline solution, alcohol, or ether. Under the action of dilute hydrochloric acid it swells up but does not dissolve, but when thus swollen is readily dissolved by a solution of pepsin.

FIG. 601.—Blood-crystals: A. Hæmoglobin crystals from human blood. B. Hæmin crystals from blood treated with acetic acid. C. Hæmatoidin crystals from an old apoplectic clot.

Serum, with the exception of its proteids, has a composition identical with that of plasma. The fibrinogen characteristic of plasma has disappeared, and the fibrin-ferment or thrombin is found instead, together with the serum albumen and serum globulin which are not involved in the process of coagulation.

The relation of the various constituents of the blood to each other may be easily understood by a reference to the subjoined plan:

Gases of the Blood.—When blood is exposed to the vacuum of an air-pump, 100 volumes are found to yield about 60 volumes of gas. The gases present are carbon dioxide, oxygen, and nitrogen, and they occur in the following proportions in arterial and venous blood:

	Carbon dioxide.	Oxygen.	Nitrogen.
Arterial blood . .	40 vols.	20 vols.	1 to 2 vols.
Venous blood . .	46 to 50 vols.	10 to 12 vols.	1 to 2 vols.

The greater quantity of the oxygen is in loose chemical combination with the hæmoglobin of the red corpuscles. The carbon dioxide exists in combination for the most part as sodium bicarbonate and carbonate. The nitrogen is in simple solution in the plasma.

Blood-crystals.—Hæmoglobin, as already stated, readily crystallizes when

separated from the blood-corpuscles. In human blood the crystals are elongated prisms (Fig. 601, *A*), and in the majority of animals belong to the rhombic system, though in the squirrel hexagonal plates are met with. Small brown prismatic crystals of *hæmin* (Fig. 601, *B*) may be obtained by mixing dried blood with common salt and boiling with a few drops of glacial acetic acid. A drop of the mixture on a slide will show the characteristic crystals on cooling. *Hæmatoidin* crystals (Fig. 601, *C*) occur sometimes in old blood-clots.

LYMPH AND CHYLE.

Lymph is a transparent, colorless or slightly yellow fluid, which is conveyed by a set of vessels named *lymphatics* into the blood. These vessels arise in nearly all parts of the body as *lymph-capillaries*. They take up the blood-plasma which has exuded from the blood-capillaries into the tissue-spaces where it has nourished the tissue-elements, and return it into the veins close to the heart, there to be mixed with the mass of blood. The greater number of these lymphatics empty themselves into one main duct, the *thoracic duct*, which passes upward along the front of the spine and opens into the large veins on the left side of the root of the neck. The remainder empty themselves into a smaller duct which terminates in the corresponding veins on the right side of the neck.

Lymph, as its name implies, is a watery fluid of sp. gr. about 1.015, closely resembling the blood-plasma, but more dilute and containing only about 5 per cent. of proteids and 1 per cent. of salts and extractives. When examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid. They are always increased in number after the passage of the lymph through lymphoid tissue, as in lymphatic glands. They are constantly furnishing a fresh supply of colorless corpuscles to the blood.

Chyle is an opaque, milky-white fluid, absorbed by the villi of the small intestine from the food, and carried by a set of vessels similar to the lymphatics, named *lacteals*, to the commencement of the thoracic duct, where it is intermingled with the lymph and poured into the circulation through the same channels. It must be borne in mind that these two sets of vessels, lymphatics and lacteals, though differing in name, are identical in structure, and that the character of the fluid they convey is different only while digestion is going on. At other times the lacteals convey a transparent, nearly colorless lymph.

Chyle exactly resembles lymph in its physical and chemical properties, except that it has, in addition to the other constituents of lymph, a quantity of finely divided fatty particles, the so-called "molecular basis of chyle," to which the milky appearance is due. It contains a little more proteid than lymph, but the chief difference lies in the large quantity of fats, soaps, lecithin, and cholesterin present in the former. Lymph and chyle, containing, as they do, fibrinogen in solution and leucocytes, clot on removal from the body, the coagulum being free from red cells, and presenting a clear or whitish jelly-like appearance.

EPITHELIUM.

All the surfaces of the body—the external surface of the skin, the internal surface of the digestive, respiratory, and genito-urinary tracts, the closed serous cavities, the inner coat of the vessels, and the acini and ducts of all secreting and excreting glands, the ventricles of the brain, and the central canal of the spinal cord—are covered by one or more layers of simple cells, called *epithelium* or *epithelial cells*. These cells are also present in the terminal parts of the organs of special sense, and in some other structures, as the pituitary and thyroid bodies. They serve various purposes, forming in some cases a protective layer, in others acting as agents in secretion and excretion, and again in others being concerned in the elaboration of the organs of special sense. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection. As the surface is worn away by the agency of friction or change of

temperature new cells are supplied, and thus the surface of the true skin and the vessels and nerves which it contains are defended from damage. In the gastrointestinal mucous membrane and in the glands the epithelial cells appear to be the principal agents in separating the secretion from the blood or from the alimentary fluids. In other situations (as the nose, fauces, and respiratory passages) the chief office of the epithelial cells appears to be to maintain an equable temperature by the moisture with which they keep the surface always slightly lubricated. In the serous cavities they also keep the opposed layers moist, and thus facilitate their movements on each other. Finally, in all internal parts they insure a perfectly smooth surface.

Of late years there has been a tendency on the part of many histologists to divide these several epithelial structures into two classes: (1) *epithelium*, consisting of nucleated protoplasmic cells, which form continuous masses on the skin and mucous surfaces and the linings of the ducts and alveoli of secreting and excreting glands; and (2) *endothelium*, which is composed of a single layer of flattened transparent squamous cells, joined edge to edge in such a manner as to form a membrane of cells. This is found on the free surfaces of the serous membranes, as the lining membrane of the heart, blood-vessels, and lymphatics; on the surface of the brain and spinal cord, and in the anterior chamber of the eye. Endothelium originates from the embryonic mesoblast, while epithelium arises, as a rule, from the epiblast or hypoblast.

Epithelium consists of one or more layers of cells united together by an interstitial cement-substance, supported on a basement-membrane, and is naturally grouped into two classes, according as to whether there is a single layer of cells (*simple epithelium*) or more than one (*stratified epithelium*). A third variety (*transitional epithelium*) is that in which cells in three or four layers are so fitted together that the appearance is not one of distinct stratification. The different varieties of simple epithelium are usually spoken of as squamous or pavement, columnar, glandular or spheroidal, and ciliated.

The *pavement epithelium* (Fig. 602) is composed of flat nucleated scales of various shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The flattening depends upon the thinness of the cell. The protoplasm of the cell presents a fine reticulum or honeycombed

FIG. 602.—Simple pavement epithelium.

FIG. 603.—Columnar epithelium from an intestinal villus.

FIG. 604.—Goblet cells. (From Kirk's *Physiology*.)

network, which gives to the cell the appearance of granulation. This kind of epithelium forms the lining of the air-cells of the lungs. The endothelium, which covers the serous membranes, and which lines the heart, bloodvessels, lymphatics, and the anterior chamber of the eye, is also of the pavement type.

The *columnar* or *cylindrical* epithelium (Fig. 603) is formed of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, more or less

flattened from mutual pressure, and are set upright on the surface on which they are supported. Their protoplasm is always more or less reticulated, and fine longitudinal striæ may be seen in it. They possess a nucleus which is oval in shape and contains an intranuclear network.

This form of epithelium covers the mucous membrane of nearly the whole gastro-intestinal tract and the glands of that part, the greater part of the

FIG. 605.—Spheroidal epithelium. Magnified 250 times.

FIG. 606.—Ciliated epithelium from the human trachea. Magnified 350 times. a. Innermost layers of the elastic longitudinal fibres. b. Homogeneous innermost layer of the mucous membrane. c. Deepest round cells. d. Middle elongated cells. e. Superficial cells, bearing cilia.

urethra, the vas deferens, the prostate, Cowper's glands, Bartholini's glands, and a portion of the uterine mucous membrane. In a modified form it also covers the ovary.

Globet- or *chalice-*cells are a modification of the columnar cell. They appear to be formed by an alteration in shape of the columnar epithelium (ciliated or otherwise) consequent on the formation of granules which consist of a substance called *mucigen* in the interior of the cell. This distends the upper part of the cell, while the nucleus is pressed down toward its deep part, until the cell bursts and the mucus is discharged on to the surface of the mucous membrane as shown in Fig. 604, the cell then assuming the shape of an open cup or chalice.

The *glandular* or *spheroidal* epithelium (Fig. 605) is composed of spheroidal or polyhedral cells, but the cells may be columnar or cubical in shape in some situ-

FIG. 607.—Epithelial cells from the oral cavity of man. Magnified 350 times. a. Large. b. Middle sized. c. The same with two nuclei.

ations. Like other forms of epithelial cells, the protoplasm is a fine reticulum, which gives to the cell the appearance of granulation. They are found in the terminal recesses of secreting glands, and the protoplasm of the cells usually contains the materials which the cells secrete.

Ciliated epithelium (Fig. 606) may be of any of the preceding forms, but usually inclines to the columnar shape. It is distinguished by the presence of minute processes, which are direct prolongations of the cell-protoplasm, like hairs or eye-

lashes (cilia), standing up from the free surface. If the cells are examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells are separate, they will often be seen to be moved about in the field by this motion.

The situations in which ciliated epithelium is found in the human body are: the respiratory tract from the nose downward to the smallest ramifications of the bronchial tube (except a part of the pharynx and the surface of the vocal cords), the tympanum and Eustachian tube, the Fallopian tube and upper portion of the uterus, the vasa efferentia, conii vasculosi, and the first part of the excretory duct of the testicle, and the ventricles of the brain and central canal of the spinal cord.

Stratified epithelium (Fig. 608) consists of several layers of cells superimposed one on the top of the other and varying greatly in shape. The cells of the deepest layer are for the most part columnar in form, and as a rule form a single layer, placed vertically on the supporting membrane; above these are several layers of spheroidal cells, which as they approach the surface become more and more compressed, until the superficial layers are found to consist of flattened scales (Fig. 607), the margins of which overlap one another, so as to present an imbricated appearance. They here undergo a chemical change from the conversion of their protoplasm into a horny substance (*keratin*).

Certain cells found in the deeper layers of stratified epithelium, and termed *prickle-cells* (Fig. 608), constitute a variety of squamous epithelium. These cells possess short fine fibrils which pass from their margins to those of neighboring cells, serving to connect them together. They are not closely connected together by cement-substance, but are separated from each other by intercellular channels, across which these fine fibrils may be seen bridging; this gives to the cell, when isolated, the appearance of being covered over with a number of short spines, in consequence of the fibrils being broken through. They were first described by Max Schultze and Virchow, and it was believed by them that the cells were dovetailed together. Subsequently this was shown not to be so by Martyn, who pointed out that the prickles were attached to each other by their apices; and recently Delépine has stated that he believes the prickles of prickles-cells are parts of fibrils forming internuclear bundles between the nuclei of the cells of an epithelium in a state of active growth (see Fig. 597).

Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are cubical, with depressions on their under surfaces, which fit on to the rounded ends of the cells of the second layer, which are pear-shaped, the apices touching the basement-membrane. Between their tapering points is a third variety of cells, filling in the intervals between them, and of smaller size than those of the other two layers (Fig. 609).

FIG. 609.—Transitional epithelium.

CONNECTIVE TISSUES.

The term **connective tissue** includes a number of tissues which possess this feature in common, viz., that they serve the general purpose in the animal economy of supporting and connecting the tissues of the body. These tissues may differ considerably from each other in appearance, but they present, nevertheless, many points of relationship, and are, moreover, developed from the same layer of the embryo, the mesoblast. They are divided into three great groups: (1) the connective tissues proper, (2) cartilage, and (3) bone. Blood, which has already been described, is, strictly speaking, a form of connective tissue, and is so dealt with by many histologists.

The Connective Tissues Proper.—Several forms or varieties of connective tissue are recognized: (1) Areolar tissue. (2) White fibrous tissue. (3) Yellow elastic tissue. (4) Mucous tissue. (5) Retiform tissue. They are all composed of a homogeneous matrix, in which are imbedded cells and fibres—the latter of two kinds, white and yellow or elastic. The distinction between the different forms of tissue depends upon the relative preponderance of one or other kind of fibre, of cells, or of matrix.

Areolar tissue (Fig. 610) is so called because its meshes are easily distended, and thus separated into areolæ or spaces, which open freely into each other, and are

FIG. 610.—Subcutaneous tissue from a young rabbit. Highly magnified. (Schäfer.)

consequently easily blown up with air, or permeated by fluid when injected into any part of the tissue. Such spaces, however, do not exist in the natural condition of the body, but the whole tissue forms one unbroken membrane composed of a number of interlacing fibres, variously superimposed. Hence the term “the cellular membrane” is in many parts of the body more appropriate than its more modern equivalent. The chief use of the areolar tissue is to bind parts together, while by the laxity of its fibres and the permeability of its areolæ it allows them to move on each other, and affords a ready exit for inflammatory and other effused fluids. It is one of the most extensively distributed of all the tissues. It is found beneath the skin in a continuous layer all over the body, connecting it to the subjacent parts. In the same way it is situated beneath the mucous and serous membranes. It is also found between muscles, vessels, and

nerves, forming investing sheaths for them, and connecting them with surrounding structures. In addition to this, it is found in the interior of organs, binding together the various lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles, etc., and thus forms one of the most important connecting media of the various structures or organs of which the body is made up. In many parts the areolæ or interspaces of areolar tissue are occupied by fat-cells, constituting *adipose tissue*, which will presently be described.

Areolar tissue presents to the naked eye a flocculent appearance, somewhat like spun silk. When stretched out, it is seen to consist of delicate soft elastic threads interlacing with each other in every direction and forming a network of extreme delicacy. When examined under the microscope (Fig. 610) it is found to be composed of white fibres and elastic fibres intercrossing in all directions, and united together by a homogeneous cement or ground-substance, the *matrix*, showing cell-spaces wherein lie many cellular elements, the *connective-tissue corpuscles*; these contain the protoplasm out of which the whole is developed and regenerated.

The white fibres are arranged in waving bands or bundles of minute transparent homogeneous filaments or fibrillæ. The bundles have a tendency to split up longitudinally or send off slips to join neighboring bundles and receive others in return, but the individual fibres are unbranched and never join other fibres; the *yellow elastic fibres* have a well-defined outline and are considerably larger in size than the white fibrillæ. They vary much, being from the $\frac{1}{24000}$ to the $\frac{1}{4000}$ of an inch in diameter. The fibres form bold and wide curves, branch, and freely anastomose with each other. They are homogeneous in appearance, and tend to curl up, especially at their broken ends.

Connective-tissue Corpuscles.—The cells of areolar tissue are of three principal kinds: (1) Flattened lamellar cells, which may be either branched or unbranched. The branched lamellar cells are composed of clear cell-substance, in which is contained an oval nucleus. The processes of these cells unite so as to form an open network, as in the cornea. The unbranched cells are joined edge to edge like the cells of an epithelium. The "tendon-cells," presently to be described, are an example of this variety. (2) Granule-cells, which are ovoid or spheroidal in shape and formed of a soft protoplasm, containing granules which are albuminous in character and stain deeply with eosin. (3) Plasma-cells of Waldeyer, varying greatly in size and form, but always to be distinguished from the other two varieties by containing a largely vacuolated protoplasm. The vacuoles are filled with fluid, and the protoplasm between the spaces is clear, with occasionally a few scattered granules.

In addition to these three typical forms of connective-tissue corpuscles, areolar tissue may be seen to possess *wandering cells*, *i. e.*, leucocytes which have emigrated from the neighboring vessels, and in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (*pigment-cells*).

FIG. 611.—White fibrous tissue. High power.

The connective-tissue corpuscles lie in spaces in the ground-substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light. This will color the ground-substance and leave the cell-spaces unstained.

The **white fibrous tissue** (Fig. 611) is a true connecting structure, and serves

three purposes in the animal economy. In the form of ligaments it serves to bind bones together; in the form of tendons, it serves to connect muscles to bones or other structures, and it forms an investing or protecting structure to various organs in the form of membranes. Examples of where it serves this latter office are to be found in the muscular fasciæ or sheaths, the periosteum, and perichondrium; the investments of the various glands (such as the tunica albuginea testis, the capsule of the kidney, etc.), the investing sheath of the nerves (epineurium), and of various organs, as the penis and the eye (sheath of the corpora cavernosa and corpus spongiosum, and of the sclerotic). In white fibrous tissue, as its name implies, the white fibres predominate, the matrix being apparent only as a cement-substance, the yellow elastic fibres comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye the appearance of silvery-white glistening fibres, covered over with a quantity of loose, flocculent tissue which binds the fibres together and carries the blood-vessels (Fig. 612). It is not possessed of any elasticity, and only the very slightest extensibility; it is exceedingly strong, so that upon the application of any external vio-

FIG. 612.—Connective tissue. (Klein and Noble Smith.) a. The white fibrous element—a layer of more or less sharply-outlined, parallel, wavy bundles of connective-tissue fibrils. On the surface of this layer is b, a network of fine elastic fibres.

FIG. 613.—Tendon of mouse's tail, stained with hæmatoxylin, showing chains of cells between the tendon-bundles. (From Quain's *Anatomy*. E. A. Schafer.)

lence the bone with which it is connected will fracture before the fibrous tissue will give way. In ligaments and tendons the bundles run parallel with each other; in membranes they intersect one another in different places. The cells occurring in white fibrous tissue are often called "tendon cells." They are situated on the surface of groups of bundles and are quadrangular in shape, arranged in rows in single file, each cell being separated from its neighbors by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (Fig. 613). Upon the addition of acetic acid to white fibrous tissue it swells up into a glassy-looking, indistinguishable mass. When boiled in water it is converted almost completely into gelatin. The white fibres being composed of the albuminoid *collagen*, which is often regarded as the anhydride of gelatin.

Yellow Elastic Tissue.—In certain parts of the body a tissue is found which when viewed in mass is of a yellowish color, and is possessed of great elasticity, so that it is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*, which may be regarded as a connective tissue in which the yellow elastic fibres

have developed to the practical exclusion of the other elements. It is found in the ligamenta subflava, in the vocal cords, in the longitudinal coat of the trachea and bronchi, in the inner coats of the blood-vessels, especially the larger arteries, and to a very considerable extent in the thyro-hyoid, crico-thyroid, and stylo-hyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (Fig. 614). In some parts, where the fibres are broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding to the intervening space. This is to be found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. The yellow elastic fibres remain unaltered by acetic acid. Chemically they are composed of the albuminoid body, *elastin*.

Vessels and Nerves of Connective Tissue.—The *blood-vessels* of connective tissue are very few—that is to say, there are few actually destined for the tissue itself,

FIG. 614.—Yellow elastic tissue. High power.

although many vessels may permeate one of its forms, the areolar tissue, carrying blood to other structures. In white fibrous tissue the blood-vessels usually run parallel to the longitudinal bundles and between them, sending transverse communicating branches across, and in some forms, as the periosteum and dura mater, they are fairly numerous. In the yellow elastic tissue the blood-vessels also run between the fibres, and do not penetrate them. *Lymphatic* vessels are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and the serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are to be found in the white fibrous tissue, where they terminate in a special manner; but it is doubtful whether any nerves terminate in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Development of Connective Tissue.—Connective tissue is developed from embryonic connective-tissue cells derived from the mesoblast. These cells, at first rounded, become fusiform and branched, and ultimately become the connective-tissue corpuscles. A mucinous intercellular substance or matrix, partly formed from the cells themselves and partly from the lymph exuded by the neighboring blood-vessels, gradually separates the cells. In the matrix the

FIG. 615.—Mucous tissue.

fibres are deposited, probably under the influence of the cells, but not by any transformation of the cell protoplasm. In the case of yellow elastic fibres, rows of granules of elastin are first laid down, these eventually fusing to form the fully developed fibre.

1. **Mucous tissue** exists chiefly in the “jelly of Wharton,” which forms the bulk of the umbilical cord, but is also found in other situations in the foetus, chiefly as a stage in the development of the connective tissue. It consists of a matrix, largely made up of mucin, in which are nucleated cells with branching and anastomosing processes (Fig. 615). Few fibres are seen in typical mucous tissue, though, at birth, the umbilical cord shows considerable development of fibres. In the adult the vitreous humor of the eye is a persistent form of mucous tissue, in which there are no fibres, and from which the cells have disappeared, leaving only the mucinous ground-substance.

FIG. 616.—Retiform connective tissue, from a lymphatic gland: most of the lymph-corpuscles are removed. (From Klein's “Elements of Histology.”) a, The reticulum. c, A capillary blood-vessel.

many mucous membranes. It is a form of connective tissue, in which the intercellular or ground-substance has, in a great measure, disappeared, and has been replaced by fluid. It is apparently composed almost entirely of extremely fine bundles of white fibrous tissue, forming an intricate network, yet chemically it yields, besides gelatin, a fresh substance, *reticulin*. The fibres are covered and concealed by flattened branched connective-tissue cells, and these must be

2. **Retiform connective tissue** is found extensively in many parts of the body, forming the framework of some organs and entering into the construction of

removed or brushed away before the fibres become visible. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid** or **adenoid tissue** (Fig. 616).

3. **Basement-membranes**, formerly described as homogeneous membranes, are really a form of connective tissue. They constitute the supporting membrane,

FIG. 617.—Adipose tissue. High power. *a*, Star-like appearance from crystallization of fatty acids.

or *membrana propria*, on which is placed the epithelium of mucous membranes or secreting glands, and in other situations. By means of staining with nitrate of silver they may be shown to consist of flattened cells in close opposition, and joined together by their edges, thus forming an example of an epithelioid arrangement of connective-tissue cells. In some situations the cells, instead of adhering by their edges, give off branching processes, which join with similar processes of other cells, and so form a network rather than a continuous membrane. In other instances basement-membranes are composed of elastic tissue, as in the cornea, or, again, in other cases of condensed ground-substance.

Adipose Tissue.—In almost all parts of the body the ordinary areolar tissue contains a variable quantity of fat. The principal situations where it is not found are the subcutaneous tissue of the eyelids, the penis and scrotum, the nymphæ, within the cavity of the cranium, and in the lungs, except near their roots. Nevertheless, its distribution is not uniform: in some parts it is collected in great abundance, as in the subcutaneous tissue, especially of the abdomen; around the kidneys; on the surface of the heart between the furrows; and in some other situations. Lastly, fat enters largely into the formation of the marrow of bones. A distinction must be made between fat and adipose tissue; the latter being a distinct issue, the former an oily matter, which in addition to forming adipose tissue is also widely present in the body, as in the fat of the brain and liver, and in the blood and chyle, etc.

Adipose tissue consists of small vesicles, *fat-cells*, lodged in the meshes of areolar tissue. The fat-cells (Fig. 617) vary in size, but of about the average

FIG. 618.—Development of fat. (Klein and Noble Smith.) *a*, Minute artery. *v*, Minute vein. *c*, Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d*, The ground-substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

diameter of $\frac{1}{500}$ of an inch. They are formed of an exceedingly delicate protoplasmic membrane, filled with fatty matter, which is liquid during life, but becomes solidified after death. They are round or spherical where they have not been subjected to pressure; otherwise they assume a more or less angular outline. A nucleus is always present, and can be easily demonstrated by staining with hæmatoxylin; in the natural condition it is so compressed by the contained oily matter as to be scarcely recognizable. These fat-cells are contained in clusters in the areolæ of fine connective tissue, and are held together mainly by a network of capillary blood-vessels, which are distributed to them.

Chemically the oily material in the cells is composed of the fats, olein, palmitin, and stearin, which are glycerin compounds with fatty acids. Sometimes fat-crystals form in the cells after death (Fig. 617, a). By boiling the tissue in ether or strong alcohol, the fat may be extracted from the vesicle, which is then seen empty and shrunken.

Fat is said to be first detected in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective-tissue corpuscles, in which small droplets of oil are formed; these coalesce to produce a larger drop, and this increases until it distends the corpuscle, the remaining protoplasm and the nucleus being crowded to the periphery of the cell (Fig. 618).

THE PIGMENT.

In various parts of the body *pigment* is found; most frequently in epithelial cells and in the cells of connective tissue. Pigmented epithelial cells are found in the external layer of the retina and on the posterior surface of the iris.

FIG. 619. — Pigment-cells from the choroid coat of the eyeball.

Pigment is also found in the epithelial cells of the deeper layers of the cuticle in some parts of the body—such as the areola of the nipple and in colored patches of skin, and especially in the skin of the colored races, and also in hair. It is also found in the epithelial cells of the olfactory region and of the membranous labyrinth of the ear.

In the *connective-tissue cells* pigment is frequently met with in the lower vertebrates. In man it is found in the choroid coat of the eye (Fig. 619) and in the iris of all but the light-blue eyes and the albino. It is also occasionally met with in the cells of retiform tissue and in the pia mater of the upper part of the spinal cord. These cells are characterized by their larger size and branched processes, which, as well as the body of the cells, are filled with granules. The pigment consists of dark-brown or black granules of very small size, closely packed together within the cells, but not invading the nucleus. Occasionally the pigment is yellow, and when occurring in the cells of the cuticle constitutes “freckles.”

THE CARTILAGE.

Cartilage is a non-vascular structure which is found in various parts of the body—in adult life chiefly in the joints, in the parietes of the thorax, and in various tubes, such as the air-passages, nostrils, and ears, which are to be kept permanently open. In the foetus at an early period the greater part of the skeleton is cartilaginous. As this cartilage is afterward replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified during the whole of life, and which is called *permanent*.

Cartilage is divided, according to its minute structure, into hyaline cartilage, fibro-cartilage, and yellow or elastic white fibro-cartilage. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, which consists entirely, or almost entirely, of cells, united in some cases by a

network of very fine fibres, in other cases apparently destitute of any intercellular substance. This is found in the external ear of rats, mice, and some other animals, and is present in the chorda dorsalis of the human embryo, but is not found in any other human structure. The various cartilages in the body are also classified, according to their function and position, into articular, interarticular, costal, and membraniform.

Hyaline cartilage, which may be taken as the type of this tissue, consists of a gristly mass of a firm consistence, but of considerable elasticity and of a pearly-bluish color. Except where it coats the articular ends of bones, it is covered externally by a fibrous membrane, the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being destitute of blood-vessels. It contains no nerves. Its intimate structure is very simple. If a thin slice is examined under the microscope, it will be found to consist of a rounded or bluntly angular form, lying in groups of two or more in a granular or almost homogeneous matrix (Fig. 620). The cells, when arranged in groups of two or more, have generally a straight outline where they are in contact with each other, and in the rest of their circumference are rounded. The cell-contents consist of clear translucent protoplasm, in which fine interlacing filaments and minute granules may sometimes be seen; imbedded in this are one or two round nuclei, having the usual intranuclear network. The cells are imbedded in cavities in the matrix, called *cartilage lacunæ*; around these the matrix is arranged in concentric lines, as if it had been formed in successive portions around the cartilage-cells. This constitutes the so-called *capsule* of the space. Each lacuna is generally occupied by a single cell, but during the division of the cells it may contain two, four, or eight cartilage-cells. By exposure to the action of an electric shock the cell assumes a jagged outline and shrinks away from the interior of the capsule.

FIG. 620.—Human cartilage-cells from the cricoid cartilage. $\times 350$.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. Some observers have shown that the matrix of hyaline cartilage, and especially the articular variety, after prolonged maceration, can be broken up into fine fibrils. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed by some histologists that the matrix is permeated by a number of fine channels, which connect the lacunæ with each other, and that these canals communicate with the lymphatics of the perichondrium, and thus the structure is permeated with a current of nutrient fluid. This, however, is somewhat doubtful.

Articular cartilage, costal cartilage, and temporary cartilage are all of the hyaline variety. They present minute differences in the size and shape of their cells and in the arrangement of their matrix. In **articular cartilage**, which shows no tendency to ossification, the matrix is finely granular under a high power; the cells and nuclei are small, and are disposed parallel to the surface in the superficial part, while nearer to the bone they become vertical. Articular cartilages have a tendency to split in a vertical direction; in disease this tendency becomes very manifest. Articular cartilage is not covered by perichondrium, on its free surface, where it is exposed to friction, though a layer of connective tissue can be traced in the adult over a small part of its circumference continuous with that of the synovial membrane, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective-tissue corpuscles of the synovial membrane.

Articular cartilage forms a thin incrustation upon the joint-surfaces of the bones, and its elasticity enables it to break the force of any concussion, while its smoothness affords ease and freedom of movement. It varies in thickness accord-

ing to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, where the greatest pressure is received; and the reverse is the case on the concave articular surfaces. Articular cartilage appears to derive its nutriment partly from the vessels of the neighboring synovial membrane, partly from those of the bone upon which it is implanted. Toynebee has shown that the minute vessels of the cancellous tissue as they approach the articular lamella dilate and form arches, and then return into the substance of the bone.

FIG. 621.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. High power.

In costal cartilage the cells and nuclei are large, and the matrix has a tendency to fibrous striation, especially in old age (Fig. 621). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is a non-vascular tissue, but is not so really, for the vessels give no branches to the cartilage substance itself, and the channels may rather be looked upon as involutions of the perichondrium. The ensiform cartilage may be regarded as one of the costal cartilages, and the cartilages of the nose and of the

larynx and trachea (except the epiglottis and cornicula laryngis, which are composed of elastic fibro-cartilage) resemble them in microscopical characters.

Temporary cartilage and the process of its ossification will be described with bone. The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, to have their matrix permeated by the salts of lime without any appearance of true bone. The process of calcification occurs also and still more frequently, according to Rollett, in such cartilages as those of the trachea and in the costal cartilages, which are prone afterward to conversion into true bone.

White fibro-cartilage consists of a mixture of white fibrous tissue and cartilaginous tissue in various proportions; it is to the first of these two constituents that its flexibility and toughness are chiefly owing, and to the latter its elasticity.

FIG. 622.—White fibro-cartilage from an intervertebral disc.

When examined under the microscope it is found to be made up of fibrous connective tissue arranged in bundles, with cartilage-cells between the bundles; these to a certain extent resemble tendon-cells, but may be distinguished from them by being surrounded by a concentrically striated area of cartilage matrix and by their being less

flattened (Fig. 622). The fibro-cartilages admit of arrangement into four groups—interarticular, connecting, circumferential, and stratiform.

1. The **interarticular fibro-cartilages** (*menisci*) are flattened fibro-cartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints. They are free on both surfaces, thinner toward their centre than at their circumference, and held in position by the attachment of their

margins and extremities to the surrounding ligaments. The synovial membrane of the joint is prolonged over them a short distance from their attached margins. They are found in the temporo-mandibular, sterno-clavicular, acromio-clavicular, wrist- and knee-joints. These cartilages are usually found in those joints which are most exposed to violent concussion and subject to frequent movement. Their use is to maintain the apposition of the opposed surfaces in their various motions; to increase the depth of the articular surfaces and give ease to the gliding movement; to moderate the effects of great pressure and deaden the intensity of the shocks to which the parts may be subjected. Humphry has pointed out that these inter-articular fibro-cartilages serve an important purpose in increasing the variety of movements in a joint. Thus, in the knee-joint there are two kinds of motion, viz., angular movement and rotation, although it is a hinge joint, in which, as a rule, only one variety of motion is permitted; the former movement takes place between the condyles of the femur and the interarticular cartilage, the latter between the cartilage and the head of the tibia. So, also, in the temporo-mandibular joint, the upward and downward movement of opening and shutting the mouth takes place between the fibro-cartilage and the jaw-bone, the grinding movement between the glenoid cavity and the fibro-cartilage, the latter moving with the jaw-bone.

2. The **connecting fibro-cartilages** are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ and between the pubic bones. They form disks, which adhere closely to both of the opposed surfaces, and are composed of concentric rings of fibrous tissue, with cartilaginous laminae interposed, the former tissue predominating toward the circumference, the latter toward the centre.

3. The **circumferential fibro-cartilages** consist of a rim of fibro-cartilage, which surrounds the margin of some of the articular cavities, as the cotyloid cavity of the hip and the glenoid cavity of the shoulder; they serve to deepen the articular surface, and to protect its edges.

4. The **stratiform fibro-cartilages** are those which form a thin coating to osseous grooves through which the tendons of certain muscles glide. Small masses of fibro-cartilages are developed also in the tendons of some muscles, where they glide over bones, as in the tendons of the *Peroneus longus* and the *Tibialis posticus*.

Yellow or elastic fibro-cartilage is found in the human body in the auricle of the external ear, the Eustachian tubes, the cornicula laryngis, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded in every direction, except immediately around each cell, where there is a variable amount of non-fibrillated hyaline, intercellular substance, by a network of yellow elastic fibres, branching and anastomosing in all directions (Fig. 623). The fibres resemble those of yellow elastic tissue, both in appearance and in being unaffected by acetic acid; and according to Rollett their continuity with the elastic fibres of the neighboring tissue admits of being demonstrated.

FIG. 623.—Yellow cartilage, ear of horse. High power.

The distinguishing feature of cartilage as to its chemical composition is that it yields on boiling a substance called *chondrin*, very similar to gelatin, but differing from it in several of its reactions. It is now believed that *chondrin* is not a simple body, but a mixture of gelatin with mucinoid substances, chief among which, perhaps, is a compound termed *chondro-mucoid*.

THE BONE.

Structure and Physical Properties of Bone.—Bone is one of the hardest structures of the animal body; it possesses also a certain degree of toughness and elasticity. Its color, in a fresh state, is of a pinkish white externally, and a deep red within. On examining a section of any bone, it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *compact tissue*; the other consists of slender fibres and lamellæ, which join to form a reticular structure; this, from its resemblance to lattice-work, is called *cancellous tissue*. The compact tissue is always placed on the exterior of the bone; the cancellous is always internal. The relative quantity of these two kinds of tissue varies in different bones, and in different parts of the same bone, as strength or lightness is requisite. Close examination of the compact tissue shows it to be extremely porous, so that the difference in structure between it and the cancellous tissue depends merely upon the different amount of solid matter, and the size and number of spaces in each; the cavities being small in the compact tissue and the solid matter between them abundant, while in the cancellous tissue the spaces are large and the solid matter in smaller quantity.

Bone during life is permeated by vessels and is enclosed, except where it is coated with articular cartilage, in a fibrous membrane, the *periosteum*, by means of which many of these vessels reach the hard tissue. If the periosteum is stripped from the surface of the living bone, small bleeding points are seen, which mark the entrance of the periosteal vessels; and on section during life every part of the bone will be seen to exude blood from the minute vessels which ramify in it. The interior of the bones of the limbs presents a cylindrical cavity filled with marrow and lined by a highly vascular areolar structure, called the *medullary membrane* or *internal periosteum*, which, however, is rather the areolar envelope of the cells of the marrow than a definite membrane.

The periosteum adheres to the surface of the bones in nearly every part, excepting at their cartilaginous extremities. When strong tendons or ligaments are attached to the bone, the periosteum is incorporated with them. It consists of two layers closely united, the outer one formed chiefly of connective tissue, containing occasionally a few fat-cells; the inner one, of elastic fibres of the finer kind, forming dense membranous networks, which can again be separated into several layers. In young bones the periosteum is thick and very vascular, and is intimately connected at either end of the bone with the epiphyseal cartilage, but less closely with the shaft, from which it is separated by a layer of soft tissue, containing a number of granular corpuscles or “osteoblasts,” in which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner, less vascular, and the osteoblasts have become converted into an epithelioid layer, which is separated from the rest of the periosteum in many places by cleft-like spaces, which are supposed to serve for the transmission of lymph. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis, when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

The marrow not only fills up the cylindrical cavity in the shafts of the long bones, but also occupies the spaces of the cancellous tissue and extends into the larger bony canals (Haversian canals) which contain the blood-vessels. It differs in composition in different bones. In the shafts of adult long bones the marrow is of a yellow color, and contains, in 100 parts, 96 of fat, 1 of areolar tissue and vessels, and 3 of fluid, with extractive matter, and consists of a matrix of fibrous tissue, supporting numerous blood-vessels and cells, most of which are fat-cells, but some are “marrow-cells,” such as occur in the red marrow, to be immediately described. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, and in the sternum and ribs,

it is of a *red* color, and contains, in 100 parts, 75 of water and 25 of solid matter, consisting of cell-globulin, nucleo-proteid, extractives, salts, and only a small proportion of fat. The red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (Fig. 624), some few of which are fat-cells, but the great majority roundish nucleated cells, the true "marrow-cells" of Kölliker. These marrow-cells proper resemble in appearance lymphoid corpuscles, and like them are amœboid. Among them may be seen smaller cells, which possess a slightly pinkish hue; these are the *erythroblasts*, from which, as we have seen, the red corpuscles of the adult are derived, and which may be regarded as descendants of the nucleated colored corpuscles of the embryo.

FIG. 624.—Cells of red marrow of the guinea-pig. (Schäfer.) *a-d*, Myeloplasmes. *e-i*, Marrow-cells proper. *j-t*, Erythroblasts—some in process of division.

Giant-cells (*myelo-plasmes*, *osteoclasts*), large, multinucleated, protoplasmic masses, are also to be found in both sorts of adult marrow, but more particularly in red marrow. They were believed by Kölliker to be concerned in the absorption of bone matrix, and hence the name which he gave to them—*osteoclasts*. They excavate small shallow pits or cavities, which are named *Howship's lacunæ*, in which they are found lying.

Vessels of Bone.—The blood-vessels of bone are very numerous. Those of the compact tissue are derived from a close and dense network of vessels ramifying in the periosteum. From this membrane vessels pass into the minute orifices in the compact tissue, running through the canals which traverse its substance. The cancellous tissue is supplied in a similar way, but by a less numerous set of larger vessels, which, perforating the outer compact tissue, are distributed to the cavities of the spongy portion of the bone. In the long bones numerous apertures may be seen at the ends near the articular surfaces, some of which give passage to the arteries of the larger set of vessels referred to; but the most numerous and largest apertures are for the veins of the cancellous tissue, which run separately from the arteries. The medullary canal in the shafts of the long bones is supplied by one large artery (or sometimes more), which enters the bone at the nutrient foramen (situated in most cases near the centre of the shaft), and perforates obliquely the compact structure. The *medullary* or *nutrient* artery, usually accompanied by one or two veins, sends branches upward and downward to supply the medullary membrane, which lines the central cavity and the adjoining canals. The ramifications of this vessel anastomose with the arteries both of the cancellous and compact tissues. In most of the flat, and in many of the short spongy bones, one or more large apertures are observed, which transmit, to the central parts of the bone, vessels corresponding to the medullary arteries and veins. The veins emerge from the long bones in three places (Kölliker): (1) by one or two large veins,

which accompany the artery; (2) by numerous large and small veins at the articular extremities; (3) by many small veins which arise in the compact substance. In the flat cranial bones the veins are large, very numerous, and run in tortuous canals in the diploic tissue, the sides of the canals being formed by a thin lamella of bone, perforated here and there for the passage of branches from the adjacent cancelli. The same condition is also found in all cancellous tissue, the veins being enclosed and supported by osseous structure and having exceedingly thin coats. When the bony structure is divided, the vessels remain patulous, and do not contract in the canals in which they are contained. Hence the occurrence of purulent absorption after amputation in those cases where the stump becomes inflamed and the cancellous tissue is infiltrated and bathed in pus.

Lymphatic vessels, in addition to those found in the periosteum, have been traced by Cruikshank, into the substance of bone, and Klein describes them as running in the Haversian canals.

Nerves are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said by Köl liker to be most numerous in the articular extremities of the long bones, in the vertebræ and the larger flat bones.

FIG. 625.—From a transverse section of the shaft of the humerus. Magnified 350 times. *a*. Haversian canals. *b*. Lacunæ, with their canaliculi in the lamellæ of these canals. *c*. Lacunæ of the interstitial lamellæ. *d*. Others at the surface of the Haversian systems, with canaliculi given off from one side.

over, on closer examination, it will be found that between these lamellæ, and therefore also arranged concentrically around the central canal, are a number of little dark specks, the *lacunæ*, and that these lacunæ are connected with each other and with the central Haversian canal by a number of fine dark lines, which radiate like the spokes of a wheel and are called *canaliculi*. All these structures—the concentric lamellæ, the lacunæ, and the canaliculi—may be seen in any single Haversian system, forming a circular district round a central, Haversian, canal. Between these circular systems, filling in the irregular intervals which are left between them, are other lamellæ, with their lacunæ and canaliculi, running in various directions, but more or less curved (Fig. 626). These are termed *interstitial lamellæ*. Again, other lamellæ, for the most part found on the surface of the bone, are arranged concentrically to the circumference of bone, constituting, as it were, a single Haversian system of the whole bone, of which the medullary cavity would represent the Haversian canal. These latter lamellæ are termed *circumferential*, or by some authors *primary* or *fundamental* lamellæ, to distinguish them from those laid down around the axis of the Haversian canals, which are then termed *secondary* or *special* lamellæ.

The *Haversian canals*, seen as round holes in a transverse section of bone at or about the centre of each Haversian system, may be demonstrated to be true

canals if a longitudinal section is made, as in Fig. 628. It will then be seen that these round holes are tubes cut across, which run parallel with the longitudinal axis of the bone for a short distance, and then branch and communicate. They vary considerably in size, some being as large as $\frac{1}{200}$ of an inch in diameter; the average size being, however, about $\frac{1}{500}$ of an inch. Near the medullary cavity the canals are larger than those near the surface of the bone. Each canal contains two blood-vessels, with a small quantity of delicate connective tissue and some nerve-filaments. In the larger ones there are also lymphatic spaces and branched cells, the processes of which communicate, through the canaliculi, with the branched processes of certain bone-cells in the substance of the bone. Those canals near the surface of the bone open upon it by minute orifices, and those near the medullary cavity open in the same way into this space, so that the whole of the bone is permeated by a system of blood-vessels running through the bony canals in the centre of the Haversian systems.

The *lamellæ* are thin plates of bone-tissue encircling the central canal, and may be compared, for the sake of illustration, to a number of sheets of paper pasted one over another around a central hollow cylinder. After macerating a piece of bone in dilute mineral acid these lamellæ may be stripped off in a lon-

FIG. 626.—Transverse section of compact tissue of bone. Magnified about 150 diameters. (Sharpey.)

gitudinal direction as thin films. If one of these is examined with a high power under the microscope, it will be found to be composed of a finely reticular structure, presenting the appearance of lattice-work made up of very slender, transparent fibres, decussating obliquely, and coalescing at the points of intersection so as to form an exceedingly delicate network. These fibres are composed of fine fibrils, identical with those of white connective tissue. The intercellular matrix between the fibres has been replaced by calcareous deposit, which the acid dissolves. In many places the various lamellæ may be seen to be held together by tapering fibres, which run obliquely through them, pinning or bolting them together. These fibres were first described by Sharpey, and were named by him *perforating fibres* (Fig. 630).

The *lacunæ* are situated between the lamellæ, and consist of a number of oblong spaces. In an ordinary microscopic section, viewed by transmitted light, they appear as dark, oblong, opaque spots, and were formerly believed to be solid cells. Subsequently, when it was seen that the Haversian canals were channels which lodge the vessels of the part, and the canaliculi, minute tubes by which the plasma of the blood circulates through the tissue, the theory was formulated that the lacunæ were hollow spaces filled during life with the same fluid, and only lined (if

lined at all) by a delicate membrane. But this view was subsequently proved to be erroneous, for examination of the structure of bone, when recent, led Virchow to believe that the lacunæ are occupied during life by a branched cell, termed a bone-cell or bone-corpuscle, the processes from which pass down the canaliculi—a view which is now universally received (Fig. 627). It is by means of these cells that the fluids necessary for nutrition are brought into contact with the ultimate tissue of bone.

The *canaliculi* are exceedingly minute channels, which pass *across* the lamellæ and connect the lacunæ with the neighboring lacunæ and also with the Haversian canal. From this central canal a number of the canaliculi are given off, which radiate from it, and open into the first set of lacunæ, arranged around the Haversian canal, between the first and second lamellæ. From these lacunæ a second set of canaliculi are given off, which pass outward to the next series of lacunæ, and so on until they reach the periphery of the Haversian system: here the canaliculi given off from the last series of lacunæ do not communicate with the lacunæ of neighboring Haversian systems, but after passing outward for a short distance form loops

FIG. 627.—Nucleated bone-cells and their processes, contained in the bone-lacunæ and their canaliculi respectively. From a section through the vertebra of an adult mouse. (Klein and Noble Smith.)

FIG. 628.—Section parallel to the surface from the shaft of the femur. Magnified 100 times. a, Haversian canals. b, Lacunæ seen from the side. c, Others seen from the surface in lamellæ which are cut horizontally.

and return to their own lacuna. Thus every part of the Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canals and traversing the canaliculi and lacunæ.

The *bone-cells* are contained in the lacunæ, which, however, they do not completely fill. They are flattened nucleated cells, which Virchow has shown are homologous with those of connective tissue. The cells are branched, and the branches, especially in young bones, pass into the canaliculi from the lacunæ.

If a longitudinal section is examined, as in Fig. 628, the structure is seen to be the same. The appearance of concentric rings is replaced by that of lamellæ or rows of lacunæ, parallel to the course of the Haversian canals, and these canals appear like half-tubes instead of circular spaces. The tubes are seen to branch and communicate, so that each separate Haversian canal runs only a short distance. In other respects the structure has much the same appearance as in transverse sections.

In sections of thin plates of bone (as in the walls of the cells which form the cancellous tissue) the Haversian canals are absent, and the canaliculi open into the spaces of the cancellous tissue (medullary spaces), which thus have the same function as the Haversian canals in the more compact bone.

Chemical Composition.—Bone consists of an animal and an earthy part intimately combined together.

The animal part may be obtained by immersing the bone for a considerable time in dilute mineral acid, after which process the bone comes out exactly the same shape as before, but perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. If now a transverse section is made (Fig. 630), the same general arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi is seen, though not so plainly, as in the ordinary section.

The earthy part may be obtained separate by calcination, by which the animal matter is completely burned out. The bone will still retain its original form, but

FIG. 629.—Lamellæ torn from a decalcified human parietal bone to show the perforating fibres of Sharpey. (Copied from a drawing by Allen Thomson.)

it will be white and brittle, will have lost about one-third of its original weight, and will crumble down with the slightest force. The earthy matter confers on bone its hardness and rigidity, and the animal matter its tenacity.

The animal basis is largely composed of *ossein*, which is identical with the collagen of white fibrous tissue, so that when boiled with water, especially under pressure, it is almost entirely resolved into gelatin.

The organic matter of bone forms about *one-third*, or 33.3 per cent.; the inorganic matter, *two-thirds*, or 66.7 per cent. Of the earthy matter, five-sixths is calcium phosphate, the remainder consisting of calcium carbonate, calcium fluoride, calcium chloride, and magnesium phosphate, with small amounts of sodium chloride and sulphate. Even after the removal of all the marrow a small percentage of fat is still found in bone.

Some of the diseases to which bones are liable mainly depend on the disproportion between the two constituents of bone. Thus in the disease called rickets, so common in the children of the poor, the bones become bent and curved, either from the superincumbent weight of the body or under the action of certain muscles. This depends upon some defect of nutrition by which bone becomes deprived of its normal proportion of earthy matter, while the animal matter is of unhealthy quality. In the vertebræ of a rickety subject Bostock found in 100 parts 79.75 animal and 20.25 earthy matter.

Development of Bone.—In the foetal skeleton some bones are preceded by

FIG. 630.—Section of bone after the removal of the earthy matter by the action of acids.

membrane, such as those forming the roof and sides of the skull; others, such as the bones of the limbs, are preceded by rods of cartilage. Hence two kinds of ossification are described: the *intramembranous* and the *intracartilaginous*.

Intramembranous Ossification.—In the case of bones which are developed in membrane no cartilaginous mould precedes the appearance of the bone-tissue. The membrane, which occupies the place of the future bone, is of the nature of connective tissue, and ultimately forms the periosteum. At this stage it is seen to be composed of fibres and granular cells in a matrix. The outer portion is more fibrous, while internally, the cells or *osteoblasts* predominate; the whole tissue is richly supplied with blood-vessels. At the outset of the process of bone formation a little network of bony spiculæ is first noticed radiating from the point or centre of ossification. When these rays of growing bone are examined with a microscope, they are found to consist at their growing point of a network of fine clear fibres and granular corpuscles with an intervening ground substance (Fig. 631). The fibres are termed *osteogenetic* fibres, and are made up of fine fibrils differing little from those of white fibrous tissue. Like them, they are probably deposited in the matrix through the influence of the cells—in this case the osteo-

FIG. 631.—Part of the growing edge of the developing parietal bone of a fetal cat. (After J. Lawrence.)

blasts. The osteogenetic fibres soon assume a dark and granular appearance from the deposition of calcareous granules in the fibres and in the intervening matrix, and as they calcify they are found to enclose some of the granular corpuscles or osteoblasts. By the fusion of the calcareous granules the bony tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The involved osteoblasts form the corpuscles of the future bone, the spaces in which they are enclosed constituting the lacunæ. As the osteogenetic fibres grow out to the periphery they continue to calcify, and give rise to fresh bone spicules. Thus a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers of bone formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently successive layers of bony tissue are deposited under the periosteum and round the larger vascular channels, which become the Haversian canals, so that the bone increases much in thickness.

Intracartilaginous Ossification.—Just before ossification begins the bone is entirely cartilaginous, and in a long bone, which may be taken as an example, the process commences in the centre and proceeds toward the extremities, which for

some time remain cartilaginous. Subsequently a similar process commences in one or more places in those extremities and gradually extends through them. The extremities do not, however, become joined to the shaft by bony tissue until growth has ceased, but are attached to it by a layer of cartilaginous tissue termed the *epiphyseal cartilage*.

The first step in the ossification of the cartilage is that the cartilage-cells, at the point where ossification is commencing and which is termed a *centre of ossification*, enlarge and arrange themselves in rows (Fig. 632). The matrix in which they are imbedded increases in quantity, so that the cells become further separated from each other. A deposit of calcareous material now takes place in this matrix,

Giant-cells or osteoclasts. *g*. *h*. Shrunken cartilage-cells. (From *Atlas of Histology*, Klein and Noble Smith.)

between the rows of cells, so that they become separated from each other by longitudinal columns of calcified matrix, presenting a granular and opaque appearance. Here and there the matrix between two cells of the same row also becomes calcified, and transverse bars of calcified substance stretch across from one calcareous column to another. Thus there are longitudinal groups of the cartilage-cells enclosed in oblong cavities, the walls of which are formed of calcified matrix, which cuts off all nutrition from the cells, and they, in consequence, waste, leaving spaces called the *primary areolæ* (Sharpey).

At the same time that this process is going on in the centre of the solid bar of cartilage of which the foetal bone consists, certain changes are taking place on

its surface. This is covered by a very vascular membrane, the *perichondrium*, entirely similar to the embryonic connective tissue already described as constituting the basis of membrane-bone, on the inner surface of which, that is to say, on the surface in contact with the cartilage, are gathered the formative cells, the *osteoblasts*. By the agency of these cells a thin layer of bony tissue is being formed between the perichondrium and the cartilage, by the *intramembranous* mode of ossification just described. There are then, in this first stage of ossification, two processes going on simultaneously: in the centre of the cartilage the formation of a number of oblong spaces, formed of calcified matrix and containing the withered cartilage-cells, and on the surface of the cartilage the formation of a layer of true membrane-bone. The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium, which has now become periosteum (Fig. 632, *ir*). The processes consist of blood-vessels and cells—*osteoblasts* or bone-formers, and *osteoclasts*, or bone-destroyers.

Newly-formed osseous substance of a lighter color. *e*. That of greater age. *f*. Lacunae with their cells. *g*. A cell still united to an osteoblast.

FIG. 635.—Vertical section from the edge of the ossifying portion of the diaphysis of a metatarsal bone from a fetal calf. (After Müller.) *a*. Ground-mass of the cartilage. *b*. Of the bone. *c*. Newly-formed bone-cells in profile, more or less imbedded in intercellular substance. *d*. Medullary canal in process of formation, with vessels and medullary cells. *e*. *f*. Bone-cells on their broad aspect. *g*. Cartilage-capsules arranged in rows, and partly with shrunken cell-bodies.

The latter are similar to the giant-cells (myelo-plaques) found in marrow, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix (Fig. 632). Wherever these processes come in contact with the calcified walls of the primary areolæ they absorb it, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* (Sharpey) or *medullary spaces* (Müller). In these secondary spaces the original cartilage-cells having disappeared, become filled with embryonic marrow, consisting of osteoblasts and vessels, and derived in the manner described above, from the osteogenetic layer of the periosteum (Fig. 633).

Thus far there has been traced the formation of enlarged spaces (secondary areolæ), the perforated walls of which are still formed by calcified cartilage-matrix, containing an embryonic marrow, derived from the processes sent in from the osteogenetic layer of the periosteum, and consisting of blood-vessels and round cells, osteoblasts (Fig. 633). The walls of these secondary areolæ are at this time of only inconsiderable thickness, but they become thickened by the deposition of layers of new bone on their interior. This process takes place in the following manner: Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as an epithelioid layer on the surface of the wall of the space (Fig. 634).

This layer of osteoblasts form a bony stratum, and thus the wall of the space becomes gradually covered with a layer of true osseous substance. On this a second layer of osteoblasts arrange themselves, and in their turn form an osseous layer. By the repetition of this process the original cavity becomes very much reduced in size, and at last only remains as a small circular hole in the centre, containing the remains of the embryonic marrow—that is, a blood-vessel and a few osteoblasts. This small cavity constitutes the Haversian canal of the perfectly ossified bone. The successive layers of osseous matter which have been laid down and which encircle this central canal constitute the lamellæ of which, as we have seen, each Haversian system is made up. As the successive layers of osteoblasts form osseous tissue, certain of the osteoblastic cells remain included between the various bony layers. These persist as the corpuscles of the future bone, the spaces enclosing them forming the lacunæ (Figs. 634 and 636). The canaliculi, at first extremely short, are supposed to be extended by absorption, so as to meet those of neighboring lacunæ.

Such are the changes which may be observed at one particular point, the centre of ossification. While they have been going on here a similar process has been set up in the surrounding parts and has been gradually proceeding toward the end of the shaft, so that in the ossifying bone all the changes described above may be seen in different parts, from the true bone in the centre of the shaft to the hyaline cartilage at the extremities. The bone thus formed differs from the bone of the adult in being more spongy and less regularly lamellated.

Thus far, then, we have followed the steps of a process by which a solid bony mass is produced, having vessels running into it from the periosteum, Haversian canals in which those vessels run, medullary spaces filled with foetal marrow, lacunæ with their contained bone-cells, and canaliculi growing out of these lacunæ.

This process of ossification, however, is not the origin of the whole of the skeleton, for even in those bones in which the ossification proceeds in a great measure from a single centre, situated in the cartilaginous shaft of a long bone, a considerable part of the original bone is formed by intramembranous ossification beneath the perichondrium or periosteum; so that the girth of the bone is increased by bony deposit from the deeper layer of this membrane. The shaft of the bone

FIG. 636.—Osteoblasts from the parietal bone of a human embryo thirteen weeks old. (After Gegenbauer.) *a*, Bony septa with the cells of the lacunæ. *b*, Layers of osteoblasts. *c*, The latter in transition to bone-corpuscles.

is at first solid, but a tube is hollowed out in it by absorption around the vessels passing into it, which becomes the medullary canal. This absorption is supposed to be brought about by large "giant-cells," the so-called osteoclasts of Kölliker (Fig. 633). They vary in shape and size, and are known by containing a large number of clear nuclei, sometimes as many as twenty. The occurrence of similar cells in some tumors of bones has led to such tumors being denominated "myeloid."

As more and more bone is removed by this process of absorption from the interior of the bone to form the medullary canal, so more and more bone is deposited on the exterior from the periosteum, until at length the bone has attained the shape and size which it is destined to retain during adult life. As the ossification of the cartilaginous shaft extends toward the articular ends it carries with it, as it were, a layer of cartilage, or the cartilage grows as it ossifies, and thus the bone is increased in length. During this period of growth the articular end, or epiphysis, remains for some time entirely cartilaginous; then a bony centre appears in it, and it commences the same process of intracartilaginous ossification; but this process never extends to any great distance. The epiphyses remain separated from the shaft by a narrow cartilaginous layer for a definite time. This layer ultimately ossifies, the distinction between shaft and epiphysis is obliterated, and the bone assumes its completed form and shape. The same remarks also apply to the processes of bone which are separately ossified, such as the trochanters of the femur. The bones, having been formed, continue to grow until the body has acquired its full stature. They increase in length by ossification continuing to extend in the epiphysial cartilage, which goes on growing in advance of the ossifying process. They increase in circumference by deposition of new bone, from the deeper layer of the periosteum, on their external surface, and at the same time an absorption takes place from within, by which the medullary cavity is increased.

The medullary spaces which characterize the cancellous tissue are produced by the absorption of the original foetal bone in the same way as the original medullary canal is formed. The distinction between the cancellous and compact tissue appears to depend essentially upon the extent to which this process of absorption has been carried; and we may perhaps remind the reader that in morbid states of the bone inflammatory absorption produces exactly the same change, and converts portions of bone naturally compact into cancellous tissue.

The number of ossific centres is different in different bones. In most of the short bones ossification commences by a single point in the centre, and proceeds toward the circumference. In the long bones there is a central point of ossification for the shaft or diaphysis; and one or more for each extremity, the epiphysis. That for the shaft is the first to appear. The union of the epiphyses with the shaft takes place in the reverse order to that in which their ossification began, with the exception of the fibula, and appears to be regulated by direction of the nutrient artery of the bone. Thus the nutrient arteries of the bones of the arm and forearm are directed toward the elbow, and the epiphyses of the bones forming this joint become united to the shaft before those at the opposite extremity. In the lower limb, on the other hand, the nutrient arteries pass in a direction from the knee: that is, upward in the femur, downward in the tibia and fibula; and in them it is observed that the upper epiphysis of the femur, and the lower epiphysis of the tibia and fibula, become first united to the shaft.

Where there is only one epiphysis, the medullary artery is directed toward that end of the bone where there is no additional centre, as toward the acromial end of the clavicle, toward the distal end of the metacarpal bone of the thumb and great toe, and toward the proximal end of the other metacarpal and metatarsal bones.

Besides these epiphyses for the articular ends, there are others for projecting parts or processes, which are formed separately from the bulk of the bone. For

an account of these the reader must be referred to the description of the individual bones in the sequel.

A knowledge of the exact periods when the epiphyses become joined to the shaft is often of great importance in medico-legal inquiries. It also aids the surgeon in the diagnosis of many of the injuries to which the joints are liable; for it not infrequently happens that, on the application of severe force to a joint, the epiphysis becomes separated from the shaft, and such injuries may be mistaken for fracture or dislocation.

THE MUSCULAR TISSUE.

The muscles are formed of bundles of reddish fibres, endowed with the property of contractility. The two principal kinds of muscular tissue found in the body are voluntary and involuntary. The former of these, from the characteristic appearances which their fibres exhibit under the microscope, are known as the "striped" muscles, and from the fact that it is capable of being put into action and controlled by the will, as "voluntary" muscle. The fibres of the latter do not present any cross-striped appearance, and for the most part are not under the control of the will; hence they are known as the "unstriped" or "involuntary" muscles. The muscular fibres of the heart differ in certain particulars from both these groups, and they are therefore separately described as "cardiac" muscular fibres.

Thus it will be seen that there are three varieties of muscular fibres: (1) Transversely striated muscular fibres, which are for the most part voluntary and under the control of the will, but some of which are not so, such as the muscles of the pharynx and upper part of the œsophagus. This variety of muscle is sometimes called *skeletal*. (2) Transversely striated muscular fibres, which are not under the control of the will—*i. e.*, the cardiac muscle. (3) Plain or unstriped muscular fibres, which are involuntary and controlled by a different part of the nervous system from that which controls the activity of the voluntary muscles. Such are the muscular walls of the stomach and intestine, of the uterus and bladder, of the blood-vessels, etc.

The **striped or voluntary muscles** are composed of bundles of fibres enclosed in a delicate web called the "perimysium," in contradistinction to the sheath of areolar tissue which invests the entire muscle, the "epimysium" (Fig. 637). The bundles are termed "fasciculi"; they are prismatic in shape, of different sizes in different muscles, and for the most part placed parallel to one another, though they have a tendency to converge toward their tendinous attachments. Each fasciculus is made up of a bundle of *fibres*, which also run parallel with each other, and which are separated from one another by a delicate connective tissue derived from the perimysium, and termed *endomysium*. This does not form the sheath of the fibres, but serves to support the blood-vessels and nerves ramifying between them. The fibres are enclosed in a separate and distinct sheath of their own, but it is not areolar tissue, and is therefore not derived from the perimysium.

A *muscular fibre* may be said to consist of a soft contractile substance enclosed in a tubular sheath, named by Bowman the *sarcolemma*. The fibres are cylindrical or prismatic in shape, and are of no great length, not exceeding, it is said, an inch and a half. They end either by blending with the tendon or aponeurosis, or else by rounded or tapering extremities which are connected to the neighboring fibres by means of the sarcolemma. Their breadth varies in man from $\frac{1}{200}$ to $\frac{1}{100}$ of an inch. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, the fibres may be

FIG. 637.—Transverse section from the sterno-mastoid in man. Magnified 50 times. *a.* External perimysium. *b.* Fasciculus. *c.* Internal perimysium. *d.* Fibre.

seen to divide into several branches. The precise mode in which the muscular fibre joins the tendon has been variously described by different observers. It may, perhaps, be sufficient to say that the sarcolemma, or membranous investment of the muscular fibre, appears to become blended with a small bundle of fibres, into which the tendon becomes subdivided, while the muscular substance terminates abruptly and can readily be made to retract from the point of junction. The areolar tissue between the fibres appears to be prolonged more or less into the tendon, so as to form a kind of sheath around the tendon bundles for a longer or shorter distance. When muscular fibres are attached to the skin or mucous membranes, their fibres are described by Hyde Salter as becoming continuous with those of the areolar tissue.

The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it will sometimes remain entire when the included substance is ruptured (see Fig. 638). On

FIG. 638.—Two human muscular fibres. Magnified 350 times. In the one, the bundle of fibrillæ (*b*) is torn, and the sarcolemma (*a*) is seen as an empty tube.

FIG. 639.—Fragments of striped muscular fibres, showing a cleavage in opposite directions. Magnified 300 diameters. *A*. Longitudinal cleavage. The longitudinal and transverse lines are both seen. Some longitudinal lines are darker and wider than the rest, and are not continuous from end to end. This results from partial separation of the fibrillæ. *c*. Fibrillæ separated from one another by violence at the broken end of the fibre, and marked by transverse lines equal in width to those on the fibre. *c'*, *c''* represent two appearances commonly presented by the separated single fibrillæ (more highly magnified). At *c'* the borders and transverse lines are all perfectly rectilinear, and the included spaces perfectly rectangular. At *c''* the borders are scalloped and the spaces bead-like. When most distinct and definite the fibrilla presents the former of these appearances. *B*. Transverse cleavage. The longitudinal lines are scarcely visible. *a*. Incomplete fracture following the opposite surfaces of a disk, which stretches across the interval, and retains the two fragments in connection. The edge and surfaces of this disk are seen to be minutely granular, the granules corresponding in size to the thickness of the disk and to the distance between the faint longitudinal lines. *b*. Another disk nearly detached. *b'*. Detached disk, more highly magnified, showing the sarcous elements.

the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in the lower animals, elongated nuclei are seen, and in connection with these a row of granules, apparently fatty, is sometimes observed.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be apparently marked by alternate light and dark bands or striæ, which pass transversely, or somewhat obliquely, round the fibre (Fig. 638). The dark and light bands are of nearly equal breadth, and alternate with great regularity. They vary in breadth from about $\frac{1}{1200}$ to $\frac{1}{1700}$ of an inch. If the surface is carefully focussed, rows of granules will be detected at the point of junction of the dark and light bands, and very fine longitudinal lines may be seen running through the dark bands and joining these granules together. By treating the specimen with certain reagents (*e. g.*, chloride of gold) fine lines may be seen running transversely between the granules, uniting them together. This appearance is believed to be due to a reticulum or network of interstitial substance lying between the contractile portions of the muscle. The longitudinal striation gives

the fibre the appearance of being made up of a bundle of fibrillæ, which have been termed *sarcostyles* or *muscle-columns*; and if the fibre is hardened in alcohol, it can be broken up longitudinally and the sarcostyles separated from each other (Fig. 639, A). The reticulum, with its longitudinal and transverse meshes, is *sarcoplasm*.

If now a transverse section of a muscular fibre is made, it is seen to be divided into a number of areas, called the *areas of Cohnheim*, more or less polyhedral in shape, and consisting of the transversely divided sarcostyles, surrounded by transparent series of sarcoplasm (Fig. 639, B, b).

Upon closer examination, and by somewhat altering the focus, the appearances become more complicated, and are susceptible of various interpretations. The transverse striation, which in Figs. 638 and 639 appears as a mere alternation of dark and light bands, is resolved into the appearance seen in Fig. 640, which shows a series of broad dark bands, separated by light bands, which are divided into two by a dark dotted line. This line is termed *Krause's membrane* (Fig. 642, K), because it was believed by Krause to be an actual membrane continuous with

FIG. 640.—Portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. B. Separated bundles of fibrils, equally magnified. a. a. Larger, and b. b, smaller collections. c. Still smaller. d. d. The smallest which could be detached.

FIG. 641.—Part of a striped muscular fibre of the water-beetle, prepared with absolute alcohol. Magnified 300 diameters. (Klein and Noble Smith.) a. Sarcolemma. b. Membrane of Krause; owing to contraction during hardening, the sarcolemma shows regular bulgings. At the side of Krause's membrane is the transparent lateral disk. Several nuclei of muscle-corpuscles are shown, and in them a minute network.

the sarcolemma, and dividing the light band into two compartments. It is now more usually regarded as being due to an optical phenomenon, from the light being reflected between disks of different refrangibility. In addition to the membrane of Krause, fine clear lines may be made out, with a sufficiently high power, crossing the centre of the dark band; these are known as the *lines of Hensen* (Fig. 642, H).

Formerly it was supposed by Bowman that a muscular fibre was made up of a number of quadrangular particles, which he named sarcous elements, joined together like so many bricks forming a column, and he came to this conclusion because he found that under the influence of certain reagents the fibre could be broken up transversely into disks, as well as longitudinally into fibrillæ (Fig. 639, B). But it is now believed that this cross-cleavage is purely artificial, and that a muscular fibre is built up of fibrillæ and not of small quadrangular particles.

Assuming that this is so, we have now to consider a little more in detail the minute structure of these longitudinal fibrillæ, or sarcostyles, as they are termed. Perhaps there are few subjects in histology which have received more attention,

and in which the appearances seen under the microscope have been more differently interpreted, than the minute anatomy of muscular fibre. Schäfer has recently worked out this subject, particularly in the wing-muscles of insects, which are peculiarly adapted for this purpose on account of the large amount of interstitial sarcoplasm which separates the sarcostyles. In the following description we shall closely follow that given by Professor Schäfer (Fig. 642).

Each sarcostyle may be said to be made up of successive portions, each of which Schäfer terms a *sarcomere*. This is the portion, situated between two membranes of Krause, which transversely divides the light band. Each sarcomere consists of a central dark part, which forms a portion of the dark band of the whole fibre, and is named by Schäfer a *sarcous element*.¹ This sarcous element really consists of two parts, superimposed one on the top of the other, and when the fibre is stretched, these two parts become separated from each other at the line of Hensen (Fig. 642, A). On either side of this central dark portion is a clear layer, most visible when the fibre is extended; this is situated between the dark centre and the membrane of Krause, and when the sarcomeres are joined together to form the sarcostyle, constitutes the light band of the striated muscular fibre.

When the sarcostyle is extended, the clear intervals are well marked and plainly to be seen; when, on the other hand, the sarcostyle is contracted, that is to say, the muscle is in a state of contraction, these clear portions are very small or they may have disappeared altogether (Fig. 642, B). When the

FIG. 642.—Diagram of a sarcomere. (After Schäfer.) A. In moderately extended condition. B. In a contracted condition. K.K. Membranes of Krause; H. Line or plane of Hensen; S.E. Poriferous sarcous element.

sarcostyle is stretched to its full extent, not only is the clear portion very well marked, but the dark portion—the sarcous element—will be seen to be separated into its two constituents along the line of Hensen.

The sarcous element does not lie free in the sarcomere, for when the sarcostyle is stretched, so as to render the clear portion visible, very fine lines, which are probably septa, may be seen running through it from the sarcous element to the membrane of Krause.

Schäfer explains these phenomena in the following way. He considers that each sarcous element is made up of a number of longitudinal channels, which open into the clear part toward the membrane of Krause, but are closed at the line of Hensen. When the muscular fibre is contracted the *clear* part of the muscular substance finds its way into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the other hand, the fibre is extended, this clear substance finds its way out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

If this view is true, it is a matter of great interest, and, as Schäfer has shown, harmonizes the contraction of muscle with the amoeboid action of proto-

¹ This must not be confused with the "sarcous element of Bowman." (See above.)

plasm. In an amœboid cell there is a framework of spongioplasm, which stains with hæmatoxylin and similar reagents, enclosing in its meshes a clear substance, hyaloplasm, which will not stain with these reagents. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out as in the formation of pseudopodia. In muscle there is the same thing: viz., a framework of spongioplasm staining with hæmatoxylin—the substance of the sarcomere—and this encloses a clear hyaloplasm, the clear substance of the sarcomere, which resists staining with this reagent. During contraction of the muscle—*i. e.*, stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—*i. e.*, when there is no stimulation—it tends to pass out of the spongioplasm.

In this way the contraction is brought about: under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium

FIG. 643.—Non-striated muscular fibre. (From Kirke's *Physiology*.)

between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. The larger vascular channels, arteries and veins, are found only in the perimysium, between the muscular fasciculi.

Nerves are profusely distributed to striped muscle. The mode of their termination will be described on a subsequent page.

The existence of *lymphatic* vessels in striped muscle has not been ascertained, though they have been found in tendons and in the sheath of the muscle.

The **unstriated plain, or involuntary muscle**, is found in the walls of the hollow viscera—viz., the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi, and the alveoli and infundibula of the lungs; in the gall-bladder and ductus communis choledochus; in the large ducts of the salivary and pancreatic glands; in the pelvis and calices of the kidney, the ureter, bladder, and urethra; in the female sexual organs—viz., the ovary, the Fallopian tubes, the uterus (enormously developed in pregnancy), the vagina, the broad ligaments, and the erectile tissue of the clitoris; in the male sexual organs—viz., the dartos of the scrotum, the vas deferens and epididymis, the vesiculæ seminales, the prostate gland, and the corpora cavernosa and corpus spongiosum; in the ducts of certain glands, as in Wharton's duct; in the capsule

and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the arteries, veins, and lymphatics: in the iris and the ciliary muscle.

Plain or unstriped muscle is made up of spindle-shaped cells, called *contractile fibre-cells*, collected into bundles and held together by a cement-substance (Fig. 643). These bundles are further aggregated into larger bundles or flattened bands, and bound together by ordinary connective tissue.

The *contractile fibre-cells* are elongated, spindle-shaped, nucleated cells of various lengths, averaging from $\frac{1}{600}$ to $\frac{1}{300}$ of an inch in length, and $\frac{1}{4500}$ to $\frac{1}{3500}$ of an inch in breadth. On transverse section they are more or less polyhedral in shape, from mutual pressure. They present a faintly longitudinal striated appearance, and consist of an elastic cell-wall containing a central bundle of fibrillæ, representing the contractile substance, and an oval or rod-like nucleus, which includes, within a membrane, a fine network communicating at the poles of the nucleus with the contractile fibres (Klein). The adhesive interstitial cement-substance, which connects the fibre-cells together, represents the endomysium, or delicate connective tissue which binds the fibres of striped muscular tissue into fasciculi; while the tissue connecting the individual bundles together represents the perimysium. The unstriped muscle, as a rule, is not under the control of the will, nor is the contraction rapid and involving the whole muscle, as is the case with the voluntary muscles. The membranes which are composed of the unstriped muscle slowly contract in a part of their extent, generally under the influence of a mechanical stimulus, as that of distention or of cold; and then the contracted part slowly relaxes while another portion of the membrane takes up the contraction. This peculiarity of action is most strongly marked in the intestines, constituting their *vermicular motion*.

Cardiac Muscular Tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are smaller by one-third, and their transverse striæ are by no means so distinct. The fibres are made up of distinct quadrangular cells joined end to end (Fig. 644). Each cell contains a clear oval nucleus, situated near the centre of the cell. The extremities of the cells have a tendency to branch or divide, the subdivisions uniting with offsets from other cells, and thus producing an anastomosis of the fibres. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

FIG. 644.—Anastomosing muscular fibres of the heart, seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically.

Development of Muscle-Fibres.—Voluntary muscular fibres are developed from the mesoblast, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibre, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of plain muscle the mesoblastic cells assume

a pointed shape at the extremities and become flattened, the nucleus also lengthening out to its permanent rod-like form.

Chemical Composition of Muscle.—In chemical composition the muscular fibres may be said, in round numbers, to consist of 75 per cent. of water, about 20 per cent. of proteids, 2 per cent. of fat, 1 per cent. of nitrogenous extractives and carbohydrates, and 2 per cent. of salts, which are mainly potassium phosphate and carbonate.

THE NERVOUS TISSUE.

The **nervous tissues** of the body are comprised in two great systems—the *cerebro-spinal* and the *sympathetic*; and each of these systems consist of a *central organ*, or series of central organs, and of *nerves*.

The *cerebro-spinal* system comprises the brain (including the medulla oblongata), the spinal cord, the cranial nerves, the spinal nerves, and the ganglia connected with both these classes of nerves. The *sympathetic* system consists of a double chain of ganglia, with the nerves which go to and come from them. It is not directly connected with the brain or spinal cord, though it is so indirectly by means of its numerous communications with the cranial and spinal nerves.

All these nervous tissues are composed chiefly of two different structures—the *gray* or *cineritious* and the *white* or *fibrous*. It is in the former, as is generally supposed, that nervous impressions and impulses originate, and by the latter that they are conducted. Hence the gray matter forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the cerebro-spinal axis; while the white matter is found in all the commissural portions of the nerve-centres and in all the cerebro-spinal nerves. The nerves of the sympathetic system are chiefly composed of a material of a somewhat different structure, which is named *gray* or *gelatinous* nerve-fibre. This form of nerve-fibre is also found in some of the cerebro-spinal nerves.

FIG. 645.—Neuroglia-cells of brain shown by Golgi's method. (After Andriezen.) (Copied from Schäfer's *Essentials of Histology*.) A. Cell with branched processes. B. Spider-cell with unbranched processes.

The **gray nervous substance** is distinguished by its dark reddish-gray color and soft consistence. It is found in the brain, spinal cord, and various ganglia intermingled with the fibrous nervous substance, and also in some of the nerves of special sense, and in gangliform enlargements which are found here and there in the course of certain cerebro-spinal nerves. It is composed of cells, commonly called *nerve-cells* or *ganglion-corporuscles*, containing nuclei and nucleoli. The cells together with the blood-vessels in the gray nerve-substance, and the nerve-fibres and vessels in the white nerve-substance, are imbedded in a peculiar ground substance, named by Virchow *neuroglia*. It consists of fibres and cells. Some of the cells are stellate in shape, and their fine processes become neuroglia-fibres, which extend radially and unbranched (Fig. 645, B) among the nerve-cells and fibres which they aid in supporting. Other cells give off fibres which branch repeatedly (Fig. 645, A). In addition to these fibres there are others which do

not appear to be connected with the neuroglia-cells. They start from the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly to terminate in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function, but is not so in development; it is epiblastic in origin, whereas all connective tissues are mesoblastic.

Each nerve-cell consists of a finely fibrillated protoplasmic material, of a reddish or yellowish-brown color, which occasionally presents patches of a deeper

tint, caused by the aggregation of pigment-granules at one side of the nucleus, as in the substantia nigra and locus cœruleus. The protoplasm also sometimes contains peculiar angular granules, which stain deeply with basic dyes, such as methylene-blue; these are known as *Nissl's granules* (Fig. 649). The nucleus is, as a rule, a large, well-defined, round, vesicular body, often presenting an intranuclear network, and containing a nucleolus which is peculiarly clear and

brilliant. The nerve-cells vary in shape and size, and have one or more processes. They may be divided for purposes of description into three groups, according to the number of processes which they possess: (1) Unipolar cells, which are found in the spinal ganglia; their single process, after a short course, divides in a T-shaped manner. (2) Bipolar cells, also found in the spinal ganglia (Fig. 648), when the cells are in an embryonic condition. They are best demonstrated in the

sympathetic ganglion-cells of a frog. Sometimes the processes come off from opposite poles of the cell, and the cell then assumes a spindle-shape; at others they both emerge at the same point. In some cases where two fibres are apparently connected with a cell, one of the

FIG. 650.—Pyramidal cell from the cerebral cortex of a mouse. (After Ramón y Cajal.)

FIG. 651.—Cell of Purkinje from the cerebellum of a cat. (After Ramón y Cajal.)

and characterized by their large size and by the tail-like processes which issue from them. The processes are of two kinds: one of them is termed the *axis-cylinder process* or *axon*, because it becomes the axis-cylinder of a nerve-fibre (Figs. 649, 650, 651). The others are termed the *protoplasmic processes* or *dendrons*; they begin to divide and subdivide as soon as they emerge from the cell, and finally end in minute twigs and become lost among the other elements of the nervous tissue.

The **white** or **fibrous** nerve-substance or *nerve-fibre* is found universally in the nervous cords, and also constitutes a great part of the brain and spinal cord. The fibres of which it consists are of two kinds, the *medullated* or *white* fibres, and the *non-medullated* or *gray* fibres.

The medullated fibres form the white part of the brain and spinal cord, and also the greater part of the cerebro-spinal nerves, and gives to these structures their opaque, white aspect. When perfectly fresh they appear to be homogeneous; but soon after removal from the body they present, when examined by transmitted light, a double outline or contour, as if consisting of two parts (Fig. 652). The central portion is named the *axis-cylinder of Purkinje*; around this is a sort of sheath of fatty material, staining black with osmic acid, named

FIG. 652.—White or medullated nerve-fibres showing the sinuous outline and double contours. (After Schäfer.)

FIG. 653.—Longitudinal section through a nerve-fibre from the sciatic nerve of a frog. $\times 830$. (After Böhm and Davidoff.)

the *white substance of Schwann*, which gives to the fibre its double contour, and the whole is enclosed in a delicate membrane, the *neurilemma*, *primitive sheath*, or *nucleated sheath of Schwann* (Fig. 652).

The *axis-cylinder* is the essential part of the nerve-fibre, and is always present; the other parts, the medullary sheath and the neurilemma, being occasionally absent, especially at the origin and termination of the nerve-fibre. It undergoes no interruption from its origin in the nerve-centre to its peripheral termination, and must be regarded as a direct prolongation of a nerve-cell. It constitutes about one-half or one-third of the nerve-tube, the whole substance being

FIG. 654.—A node of Ranvier of a medullated nerve-fibre, viewed from above, magnified about 750 diameters. The medullary sheath is discontinuous at the node, whereas the axis-cylinder passes from one segment into the other. At the node the sheath of Schwann appears thickened. (Klein and Noble Smith.)

greater in proportion in the nerves than in the central organs. It is perfectly transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils, which stain darkly with gold chloride (Fig. 653). At its termination the axis-cylinder of a nerve-fibre may be seen to break up into fibrillæ, confirming the view of its structure. These fibrillæ have been termed the *primitive fibrillæ* of Schultze. The axis-cylinder is said by some to be enveloped in a special, reticular sheath, which separates it from the white matter of Schwann, and is composed of a substance called *neurokeratin*. The more common opinion is that this network or reticulum is contained in the white matter of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it. The *medullary sheath* or *white matter of Schwann* (Fig. 653) is regarded as being a fatty matter in a fluid state, which insulates and protects the essential part of the nerve—the axis-cylinder. The white matter varies in thickness to a very

considerable extent, in some forming a layer of extreme thinness, so as to be scarcely distinguishable; in others forming about one-half the nerve-tube. The size of the nerve-fibres, which varies from $\frac{1}{2000}$ to $\frac{1}{1200}$ of an inch, depends mainly upon the amount of the white substance, though the axis-cylinder also varies in size within certain limits. The white matter of Schwann does not always form a continuous sheath to the axis-cylinder, but undergoes interruptions in its continuity at regular intervals, giving to the fibre the appearance of constriction at these points. These were first described by Ranvier, and are known as the *nodes of Ranvier* (Fig. 654). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurilemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. In addition to these interruptions oblique clefts may be seen in the medullary sheath, subdividing it into irregular portions, which are termed *medullary segments*, or *segments of Lantermann* (Fig. 653). There is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined, frequently present a beaded or varicose appearance: this is due to manipulation and pressure causing the oily matter to collect into drops, and in consequence of the extreme delicacy of the primitive sheath, even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the membrane. This is, of course, promoted by the action of certain reagents.

The *neurilemma* or *primitive sheath* (sometimes called the *tubular membrane* or *sheath of Schwann*) presents the appearance of a delicate, structureless membrane. Here and there beneath it, and situated in depressions in the white matter of Schwann, are nuclei surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and bear a definite relation to the nodes of Ranvier; one nucleus generally lying in the centre of each internode. The primitive sheath is not present in all medullated nerve-fibres, being absent in those fibres which are found in the brain and spinal cord.

Non-medullated Fibres.—Most of the nerves of the sympathetic system, and some of the cerebro-spinal, consist of another variety of nervous fibres, which are called the *gray* or *gelatinous* nerve-fibres—*fibres of Remak* (Fig. 655). These consist of a central core or axis-cylinder enclosed in a nucleated sheath, which tends to split into fibrillæ, and is probably of the nature of neurokeratin. In external appearance the gelatinous nerves are semi-transparent and gray or yellowish-gray. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

Development of Nerve-cells and Fibres.—The nerve-cells are developed from certain of the cells which line the neural canal or form the neural crest of the embryo (see section on Development). Some of these cells assume a rounded form and are termed *neuroblasts*, and from each neuroblast there grows out a process, the axis-cylinder process or axon, and subsequently the branching processes or dendrons. The axis-cylinders, at first naked, acquire their medullary sheath, possibly by some metamorphosis of their outer layer. The neurilemma is thought to be derived from mesoblastic cells which become flattened and wrapped round the fibre, the cement-substance at their apposed ends forming the material which stains with silver nitrate at the nodes of Ranvier. Nerve-cells in the sympathetic and peripheral ganglia take their origin from small collections of neuroblasts, which are split off from the rudimentary spinal ganglia. Cells which are, originally, similar to neuroblasts seem to give rise to neuroglia-cells, numerous processes sprouting from the cell to form the neuroglial fibres.

FIG. 655.—A small nervous branch from the sympathetic of a mammal. *a*, Two medullated nerve-fibres among a number of gray nerve-fibres, *b*.

Chemical Composition.—The amount of water in nervous tissue varies with the situation. Thus in the gray matter of the cerebrum it constitutes about 83 per cent., in the white matter from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent. The solids consist of proteids (in the gray matter they form half the total solids), neurokeratin, nuclein, protagon, lecithin, cerebroside, cholesterin, nitrogenous extractives, and salts, with some gelatin and fat from the adherent connective tissue.

The nervous structures are divided, as before mentioned, into two great systems, viz., the *cerebro-spinal*, comprising the brain and spinal cord, the nerves connected with these structures, and the ganglia situated on them; and the *sympathetic*, consisting of a double chain of ganglia and the nerves connected with them. All these structures require separate consideration; they are composed of the two

kinds of nervous tissue above described, intermingled in various proportions, and having, in some parts, a very intricate arrangement.

The brain or *encephalon* is that part of the cerebro-spinal system which is contained in the cavity of the skull. It is divided into several parts, which will be described in the sequel. In these parts the gray or vesicular nervous matter is found partly on the surface of the brain, forming the convolutions of the cerebrum and the laminae of the cerebellum. Again, gray matter is found in the interior of the brain, collected into large and distinct masses or ganglionic bodies, such as the corpus striatum, optic thalamus, and corpora quadrigemina. Finally, gray matter is found intermingled intimately with the white, but without definite arrangement, as in the gray matter in the pons Varolii and the floor of the fourth ventricle.

The white matter of the brain is divisible into three distinct classes of fibres: (1) Diverging or peduncular

fibres, which connect the hemispheres with the medulla oblongata and the spinal cord. (2) Commissural fibres, which connect together the two hemispheres. (3) Association fibres, which connect different parts of the same hemisphere.

The manner in which these fibres are intermingled with each other and with the gray matter in the brain and spinal cord is very intricate, and can be fully understood only by a careful study of the details of its descriptive anatomy in the sequel. The further consideration of this subject will therefore be deferred until after the description of the various divisions of which the cerebro-spinal system is made up.

The nerves are round or flattened cords, formed of the nerve-fibres already described. They are connected at one end with the cerebro-spinal centre or with the ganglia, and are distributed at the other end to the various textures of the body; they are subdivided into two great classes—the *cerebro-spinal*, which proceed from the cerebro-spinal axis, and the *sympathetic* or *ganglionic* nerves, which proceed from the ganglia of the sympathetic. The *cerebro-spinal* nerves consist of numerous nerve-fibres collected together and enclosed in a membranous sheath (Fig. 656). A small bundle of primitive fibres, enclosed in a tubular sheath, is called a *funiculus*; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or

FIG. 656.—Transverse section through a microscopic nerve, representing a compound nerve-bundle, surrounded by perineurium. Magnified 120 diameters. The medullated fibres are seen as circles with a central dot—viz., medullary sheath and axis-cylinder—in transverse section. They are embedded in endoneurium, containing numerous nuclei, which belong to the connective-tissue cells of the latter. (Klein and Noble Smith.) p. Perineurium, consisting of laminae of fibrous connective-tissues, alternating with flattened nucleated connective-tissue cells. l. Lymph-space between epineurium and surface of nerve-bundle.

fasciculi, which are bound together in a common membranous investment, and constitute the nerve.

In structure the common membranous investment, or sheath of the whole nerve, which is called the *epineurium*, as well as the *septa* given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi, called the *perineurium*, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue, which has a distinctly lamellar arrangement, consisting of several lamellæ, separated from each other by spaces containing lymph. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue called the *endoneurium*. It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground-substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebro-spinal nerves consist almost exclusively of the medullated nerve-fibres, the non-medullated existing in very small proportions.

The blood-vessels supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres accompany these capillary vessels, *vaso-motor fibres*, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain medullated fibres as running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed *nervi nervorum*, are considered by him to have an important bearing upon certain neuralgic pains.

The nerve-fibres, as far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the nerve-fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve-fibres, and again pass on, to become blended with the nerve-fibres in some adjoining funiculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve.

The communications which take place between two or more nerves form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nervous trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual filaments remain separate and distinct, and do not inosculate with one another.

It is probable that through this interchange of fibres the different branches passing off from a plexus have a more extensive connection with the spinal cord than if they each had proceeded to be distributed without such connection with other nerves. Consequently the parts supplied by these nerves have more extended

relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic nerves** are constructed in the same manner as the cerebro-spinal nerves, but consist mainly of non-medullated fibres, collected into funiculi, and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres, and the amount varies in different nerves, and may be known by their color. Those branches of the sympathetic which present a well-marked gray color are composed more especially of gelatinous nerve-fibres, intermixed with a few medullated fibres; while those of a white color contain more of the latter fibres and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerve-fibres, both of the cerebro-spinal and sympathetic system, convey impressions of a twofold kind. The sensory nerves, called also *centripetal* or *afferent* nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The *motor* nerves, called also *centrifugal* or *efferent* nerves, transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origin and Termination of Nerves.—By the expression “the termination of nerve-fibres” is signified their connection with the nerve-centres, and with the parts they supply. The former are sometimes called their *origin*, or *central* termination; the latter their *peripheral* termination. The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve-centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor and the posterior sensory. The point where the nerve root or roots emerge from the nervous centre is named the *superficial* or *apparent* origin, but the fibres of which the nerve consists can be traced for a certain distance into the nervous centre to some portion of the gray substance, which constitutes the *deep* or *real* origin of the nerve.

The manner in which these fibres arise at their deep origin varies with their functions. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the gray substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inward either from nerve-cells in the organs of special sense (*e. g.*, the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre, they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Peripheral Terminations of Nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves, respectively. Sensory nerves would appear to terminate either in *minute primitive fibrillæ* or networks of these; or else in special terminal organs, which have been termed *peripheral end-organs*, and of which there are several principal varieties, viz., the end-bulbs of Krause, the tactile corpuscles of Wagner, the Pacinian corpuscles, and the neuro-tendinous and neuro-muscular spindles.

Termination in Fibrillæ.—When a medullated nerve-fibre approaches its termination, the white matter of Schwann suddenly disappears, leaving only the axis-cylinder, surrounded by the neurilemma, and forming a non-medullated fibre. This, after a time, loses its neurilemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrils. Finally, the axis-cylinder breaks up into its constituent primitive nerve-fibrillæ, which often present regular varicosities and anastomose

with one another, thus forming a network. This network passes between the elements of the tissue to which the nerves are distributed, which is always epithelial, the nerve-fibrils lying in the interstitial substance between the epithelial cells, and there terminating, though some observers maintain that the actual terminations are within the cells. In this way nerve-fibres have been found to terminate in the epithelium of the skin and mucous membranes, and in the anterior epithelium of the cornea.

The **end-bulbs of Krause** (Fig. 657) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective-tissue sheath of a medullated fibre, and containing a soft semifluid core in which the termination of the axis-cylinder is situated, ending either as a bulbous extremity, or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye, where they are spheroidal in shape in man, but cylindrical in most other animals, in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the genital organs of both sexes, the penis in the male, and the clitoris in the female. In this situation they have a mulberry-like appearance, from being constricted by connective-tissue septa into from two to six knob-like masses, and have received the name of *genital corpuscles*. Very similar corpuscles are found in the epineurium of nerve-trunks. In the synovial membrane of certain joints (*e. g.*, those of the fingers), rounded or oval end-bulbs have been found; these are designated *articular end-bulbs*.

Tactile corpuscles have been described by Grandry as occurring in the papillæ of the beak and tongue of birds, and by Merkel as occurring in the papillæ and epithelium of the skin of man and animals, especially in those parts of the skin devoid of hair. They consist of a capsule composed of a very delicate, nucleated membrane, and contain two or more granular, somewhat flattened cells, between which the medullated nerve-fibre, which enters the capsule by piercing its investing membrane, is supposed to terminate.

FIG. 657.—End-bulb of Krause. *a*. Medullated nerve-fibre. *b*. Capsule of corpuscle. (From Klein's *Elements of Histology*.)

FIG. 658.—Tactile papilla of the hand treated with acetic acid. Magnified 350 times. *A*. Side view of a papilla of the hand. *a*. Cortical layer. *b*. Tactile corpuscle, with transverse nuclei. *c*. Small nerve of the papilla, with neurilemma. *d*. Its two nervous fibres running with spiral coils around the tactile corpuscle. *e*. Apparent termination of one of these fibres. *B*. A tactile papilla seen from above, so as to show its transverse section. *a*. Cortical layer. *b*. Nerve-fibre. *c*. Outer layer of the tactile body, with nuclei. *d*. Clear interior substance.

The **tactile corpuscles** (Fig. 658), described by Wagner and Meissner, are oval-shaped bodies, made up of connective tissue, and consisting of a capsule, and imperfect membranous septa, derived from it, which penetrate its interior. The axis-cylinder of the medullated fibres passes through the capsule, and having entered the corpuscle terminates in a small globular or pyriform enlargement, near the inner surface of the capsule. These tactile corpuscles have been described as occurring in the papillæ of the corium of the hand and foot, the front of the

forearm, skin of the lips, and the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the nipple. They are not found in all the papillæ; but from their existence in those parts in which the skin is highly sensi-

FIG. 659.—Nerve-ending of Ruffini. (After A. Ruffini, *Arch. ital. de Biol.*, Turin, t. xxi. 1894.)

tive, it is probable that they are specially concerned in the sense of touch, though their absence from the papillæ of other tactile parts shows that they are not essential to this sense.

Ruffini has described a special variety of nerve-ending in the subcutaneous tissue of the human finger (Fig. 659). These are usually known as *Ruffini's endings*. They are principally situated at the junction of the corium with the subcutaneous tissue; they are oval in shape, and consist of a strong connective-tissue sheath, inside which the nerve-fibre divides into numerous branches, which show varicosities and end in small free knobs. They resemble the corpuscles of Golgi.

FIG. 660.—Pacinian corpuscle, with its system of capsules and central cavity. *a.* Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces, and one penetrates to the central capsule. *b.* The fibrous tissue of the stalk prolonged from the perineurium. *n.* Nerve-tube advancing to the central capsule, there losing its white matter, and stretching along the axis to the opposite end, where it is fixed by a tubercular enlargement.

The **Pacinian corpuscles**¹ (Fig. 660) are found in the human subject chiefly on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes, lying in the subcutaneous tissue; but they have also been described as connected with the nerves of the joints, and in some other situations, as the mesentery of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellæ or capsules, arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent material, in the middle of which is the single medullated fibre, which traverses the space to near its distal extremity. Here it terminates in a rounded knob or end, sometimes bifurcating previously, in which case each branch has a similar arrangement. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space.

¹ Often called in German anatomical works "corpuscles of Vater."

Other authors describe the artery as entering the corpuscle at the pole opposite to the nerve-fibre.

Herbst has described a somewhat similar "nerve-ending" to the Pacinian corpuscle, as being found in the mucous membrane of the tongue of the duck and in some other situations. It differs, however, from the Pacinian corpuscles, in being smaller, its capsules thinner and more closely approximated, and especially in the fact that the axis-cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the *corpuscles of Herbst*.

FIG. 661.—Organ of Golgi (neuro-tendinous spindle) from the human tendon Achillis. (After Ciaccio.)

Neuro-tendinous spindles.—The nerves supplying tendons have a special modification of the terminal fibres, especially numerous at the point where the tendon is becoming muscular. The tendon bundles become enlarged, and the nerve-fibres—one, two, or more in number—penetrate between the fasciculi of the tendon and spread out between the fibres to end in irregular discs or varicosities. A spindle-shaped body is thus formed, composed of tendon bundles and nerve-fibres, which is known as the *organ of Golgi* (Fig. 661).

FIG. 662.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

Neuro-muscular spindles.—In the majority of voluntary muscles there have been found special end-organs consisting of a small bundle of peculiar muscular fibres (intrafusal fibres), embryonic in type, invested by a capsule within which

nerve-fibres, experimentally shown to be sensory in origin, terminate. These neuro-muscular spindles vary in length from $\frac{1}{30}$ to $\frac{1}{5}$ of an inch and have a distinctly fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule they divide several times, and, losing their medulla, ultimately end in naked axis-cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid or rounded discs (Fig. 662). Neuro-muscular spindles have not yet been demonstrated in the tongue or eye muscles.

In the organs of special sense the nerves appear to terminate in cells which belong to the epithelial class, and have received the name of *sensory* or *nerve-epithelium* cells. This is not, however, the real state of the case; the nerve-fibre is in reality a process from the epithelial cell, and terminates by branching around a ganglion-cell. The stimulus carried by it is continued onward by an axis-cylinder, derived from the ganglion, to the brain. These nerve-epithelium cells must therefore be regarded as modified forms of nerve-cells. They will be more particularly described in the sequel, in connection with the description of the organs of special sense.

FIG. 663.—Muscular fibres of *Lacerta viridis* with the terminations of nerves. *a*. Seen in profile. P.P. The nerve end-plates. S.S. The base of the plate, consisting of a granular mass with nuclei. *b*. The same as seen in looking at a perfectly fresh fibre, the nervous ends being probably still excitable. (The forms of the variously-divided plate can hardly be represented in a woodcut by sufficiently delicate and pale contours to reproduce correctly what is seen in nature.) *c*. The same as seen two hours after death from poisoning by curare.

Motor nerves are to be traced either into unstriped or striped muscular fibres. In the unstriped or involuntary muscles the nerves are derived from the sympathetic, and are composed mainly of the non-medullated fibres. Near their termination they divide into a number of branches, which communicate and form an intimate plexus. At the junction of the branches small triangular nuclear bodies (ganglion-cells) are situated. From these plexuses minute branches are given off, which divide and break up into the ultimate fibrillæ of which the nerve is composed. These fibrillæ course between the involuntary muscle-cells, and, according to Elischer, terminate on the surface of the cell, opposite the nucleus, in a minute swelling. Arnold and Frankenhäuser believed that these ultimate fibrillæ penetrated the muscular cell and ended in the nucleus. More recent observation, however, has tended to disprove this.

In the striped or voluntary muscle, the nerves supplying the muscular fibres are derived from the cerebro-spinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres, or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre is long, more than one nerve-fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described them, *motorial end-plates* (Fig. 663).¹ The nerve-fibre,

¹ They had, however, previously been noticed, though not accurately described, by Doyère, who named them "nerve-hillocks."

on approaching the muscular fibre, suddenly loses its white matter of Schwann, which abruptly terminates; the neurilemma becomes continuous with the sarcolemma of the muscle, and only the axis-cylinder enters the muscular fibre, where it immediately spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and is imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

The **Ganglia** may be regarded as separate small aggregations of nerve-cells, connected with each other, with the cerebro-spinal axis, and with the nerves in various situations. They are found on the posterior root of each of the spinal nerves; on the posterior or sensory root of the fifth cranial nerve; on the facial and auditory nerves; and on the glosso-pharyngeal and pneumogastric nerves. They are also found in a connected series along each side of the vertebral column, forming the trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other or with branches of the cerebro-spinal system. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely adhering membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the blood-vessels supplying its substance.

In structure all ganglia are essentially similar (Fig. 664), consisting of the same structural elements as the other nervous centres, viz., a collection of nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath, which is continuous with the sheath of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves are pyriform in shape, and have only one process, the axis-cylinder or axon. A short distance from the cell, and while still within the ganglion, this process divides in a T-shaped manner, one limb of the cross-bar passing centrally and forming the central portion of a sensory nerve-fibre; the other limb passing peripherally to form the axis-cylinder process of the peripheral nerve-fibre. In the sympathetic ganglia the nerve-cells are multipolar and have one axis-cylinder process or axon and several protoplasmic processes or dendrons. The former of these emerges from the ganglion as a non-medullated nerve-fibre. Similar cells are found in the ganglia connected with the fifth cranial nerve, and these ganglia are therefore regarded by some as the cranial portions of the sympathetic system. The nerve-cells are disposed in the ganglia in groups of varying size, and these groups are separated from each other by bundles of nerve-fibres, some of which traverse the ganglia without being connected with the cells.

FIG. 664.—Section through a microscopic ganglion. Magnified 300 diameters. (Klein and Noble Smith.) *c*. Capsule of the ganglion. *n*. Nerve-fibres passing out of the ganglion. The nerve-fibres which entered the ganglion are not represented. The nerve-fibres are ordinary medullated fibres, but the details of their structure are not shown, owing to the low magnifying power. The ganglion-cells are invested by special capsules, lined by a few nuclei, which are here represented as if contained in the capsule.

THE VASCULAR SYSTEM.

The **Vascular System**, exclusive of its central organ, the heart, is divided into four classes of vessels: the arteries, capillaries, veins, and lymphatics; the minute structure of these vessels will be briefly described here, the reader being referred to the body of the work for the details of their ordinary anatomy.

Structure of Arteries (Fig. 665).—The arteries are composed of three coats: internal or endothelial coat (*tunica intima* of Kölliker); middle muscular coat (*tunica media*); and external connective-tissue coat (*tunica adventitia*).

FIG. 665.—Transverse section through a small artery and vein of the mucous membrane of the epiglottis of a child. Magnified about 350 diameters. (Klein and Noble Smith.) A. Artery, showing the nucleated endothelium, *e*, which lines it: the vessel being contracted, the endothelial cells appear very thick. Underneath the endothelium is the wavy elastic intima. The chief part of the wall of the vessel is occupied by the circular muscle-coat *m*; the staff-shaped nuclei of the muscle-cells are well seen. Outside this is *a*, part of the adventitia. This is composed of bundles of connective-tissue fibres, shown in section, with the nuclei of the connective-tissue corpuscles. The adventitia gradually merges into the surrounding connective tissue. V. Vein showing a thin endothelial membrane, *e*, raised accidentally from the intima, which on account of its delicacy is seen as a mere line on the media *m*. This latter is composed of a few circular unstriped muscle-cells. *a*. The adventitia, similar in structure to that of an artery.

The two inner coats together are very easily separated from the external, as by the ordinary operation of tying a ligature on an artery. If a fine string be tied forcibly upon an artery and then taken off, the external coat will be found undivided, but the internal coats are divided in the track of the ligature and can easily be further dissected from the outer coat. The *inner coat* can be separated from the middle by a little maceration, or it may be stripped off in small pieces; but, on account of its friability, it cannot be separated as a complete membrane. It is a fine, transparent, colorless structure which is highly elastic, and is commonly corrugated into longitudinal wrinkles. The inner coat consists of—

1. A layer of pavement-endothelium, the cells of which are polygonal, oval, or fusiform, and have very distinct round or oval nuclei. This endothelium is brought into view most distinctly by staining with nitrate of silver.
2. A subendothelial layer, consisting of delicate connective tissue with branched cells lying in the interspaces of the tissue. In arteries of less than a line in diameter the subendothelial layer consists of a single stratum of stellate cells, and the connective tissue is only largely developed in vessels of a considerable size.
3. An elastic or fenestrated layer, which consists of a mem-

brane containing a network of elastic fibres, having principally a longitudinal direction and in which, under the microscope, small, elongated apertures or perforations may be seen, giving it a fenestrated appearance. It was therefore called by Henle the *fenestrated membrane*. This membrane forms the chief thickness of the inner coat, and can be separated into several layers, some of which present the appearance of a network of longitudinal elastic fibres, and others present a more membranous character, marked by pale lines having a longitudinal direction. The fenestrated membrane in microscopic arteries is a very thin layer, but in the larger arteries, and especially in the aorta, it has a very considerable thickness.

The *middle coat* (*tunica media*) is distinguished from the inner by its color and by the transverse arrangement of its fibres, in contradistinction to the longitudinal direction of those of the inner coat. In the smaller arteries it consists principally of muscular tissue, being made up of plain muscle-fibres in fine bundles, arranged in lamellæ and disposed circularly around the vessel. These lamellæ vary in number according to the size of the vessel; the very small arteries having only a

single layer, and those not larger than one-tenth of a line in diameter three or four layers. It is to this coat that the great thickness of the walls of the artery is

FIG. 666.—Longitudinal section of artery and vein. *a*, an artery from the mesentery of a child, .062", and *b*, vein .067" in diameter, treated with acetic acid and magnified 350 times. *a*. Nuclei of the endothelial cells. *δ*. Elastic longitudinal fibrous coat.

mainly due (Fig. 665, A, m). In the larger vessels, as the iliac, femoral, and carotid, elastic fibres unite to form lamellæ, which alternate with the layers of

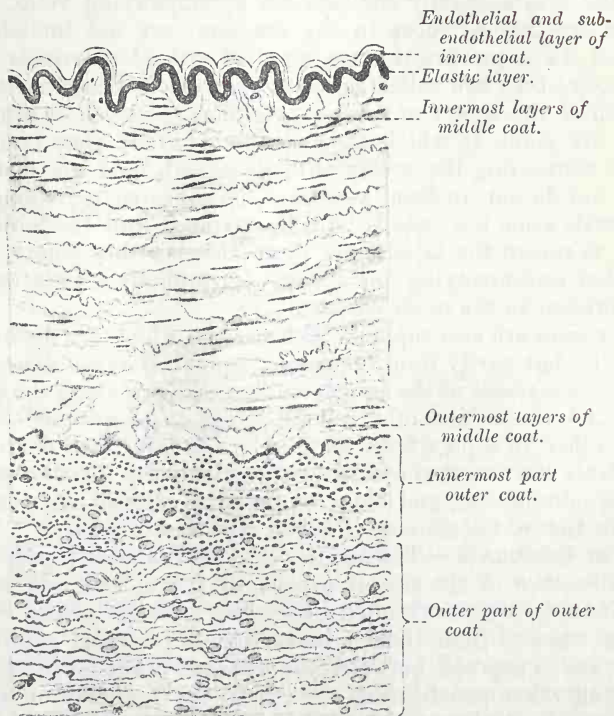

FIG. 667.—Section of a medium-sized artery. (After Grünstein.)

muscular fibre and are united by elastic fibres which pass between the muscular bundles, and are connected with the fenestrated membrane of the inner coat (Fig. 667). In the largest arteries, as the aorta and innominate, the amount of elastic

tissue is very considerable. In these vessels also bundles of white connective tissue have been found in small quantities in the middle coat. The muscle-fibre cells of which the middle coat is made up are about $\frac{1}{500}$ of an inch in length, and contain well-marked, rod-shaped nuclei, which are often slightly curved.

The *external coat* (*tunica adventitia*) consists mainly of fine and closely felted bundles of white connective tissue, but also contains elastic fibres in all but the smallest arteries. The elastic tissue is much more abundant next the tunica media, and is sometimes described as forming here, between the adventitia and media, a special layer, the *tunica elastica externa* of Henle. This layer is most marked in arteries of medium size. In the largest vessels the external coat is relatively thin; but in small arteries it is of greater proportionate thickness. In the smaller arteries it consists of a single layer of white connective tissue and elastic fibres; while in the smallest arteries, just above the capillaries, the elastic fibres are wanting, and the connective tissue, of which the coat is composed, becomes more homogeneous the nearer it approaches the capillaries, and is gradually reduced to a thin membranous envelope which finally disappears.

Some arteries have extremely thin coats in proportion to their size; this is especially the case in those situated in the cavity of the cranium and spinal canal, the difference depending on the greater thinness of the external and middle coats.

The arteries, in their distribution throughout the body, are included in a thin fibro-areolar investment, which forms what is called their *sheath*. In the limbs this is usually formed by a prolongation of the deep fascia; in the upper part of the thigh it consists of a continuation downward of the transversalis and iliac fasciæ of the abdomen; in the neck, of a prolongation of the deep cervical fascia. The included vessel is loosely connected with its sheath by a delicate areolar tissue; and the sheath usually encloses the accompanying veins, and sometimes a nerve. Some arteries, as those in the cranium, are not included in sheaths.

All the larger arteries are supplied with blood-vessels like the other organs of the body; they are called the *vasa vasorum*. These nutrient vessels arise from a branch of the artery or from a neighboring vessel, at some considerable distance from the point at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and are distributed to the external coat, but do not, in man, penetrate the other coats; though in some of the larger mammals some few vessels have been traced into the middle coat. Minute veins serve to return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymphatic vessels and lymphatic spaces are also present in the outer coat.

Arteries are also supplied with nerves, which are derived chiefly from the sympathetic, but partly from the cerebro-spinal system. They form intricate plexuses upon the surfaces of the larger trunks, and run along the smaller arteries as single filaments or bundles of filaments, which twist around the vessel and unite with each other in a plexiform manner. The branches derived from these plexuses penetrate the external coat, and are principally distributed to the muscular tissue of the middle coat, and thus regulate, by causing the contraction and relaxation of this tissue, the amount of blood sent to any part.

The Capillaries.—The smaller arterial branches (excepting those of the cavernous structure of the sexual organs, of the spleen, and in the uterine placenta) terminate in a network of vessels which pervade nearly every tissue of the body. These vessels, from their minute size, are termed capillaries (*capillus*, a hair). They are interposed between the smallest branches of the arteries and the commencing veins, constituting a network, the branches of which maintain the same diameter throughout; the meshes of the network being more uniform in shape and size than those formed by the anastomoses of the small arteries and veins.

The *diameter* of the capillaries varies in the different tissues of the body, their usual size being about $\frac{1}{3000}$ of an inch. The smallest are those of the brain and

the mucous membranes of the intestines; and the largest those of the skin and the marrow of bone, where they are stated to be as large as $\frac{1}{1200}$ of an inch.

The *form* of the capillary net varies in the different tissues, the meshes being generally rounded or elongated. The *rounded form of mesh* is most common, and prevails where there is a dense network, as in the lungs, in most glands and mucous membranes, and in the cutis; here the meshes are more or less angular, sometimes nearly quadrangular or polygonal; or more often irregular and not of an absolutely circular outline.

Elongated meshes are observed in the muscles and nerves, the meshes being usually of a parallelogram form, the long axis of the mesh running parallel with the long axis of the nerve and fibre. Sometimes the capillaries have a *looped* arrangement; a single vessel projecting from the common network and returning after forming one or more loops, as in the papillæ of the tongue and skin. The number of the capillaries, and the size of the meshes, determine the degree of vascularity of a part. The closest network and the smallest interspaces are found in the lungs and in the choroid coat of the eye. In these situations the inter-

spaces are smaller than the capillary vessels themselves. In the kidney, in the conjunctiva, and in the cutis the interspaces are from three to four times as large as the capillaries which form them; and in the brain from eight to ten times as large as the capillaries in their long diameter, and from four to six times as large in their transverse diameter. In the adventitia of arteries the width of the meshes is ten times that of the capillary vessels. As a general rule, the more active the function of the organ, the closer is its capillary net and the larger its supply of blood; the meshes of the network being very narrow in all growing parts, in the glands, and in the mucous membranes; wider in bones and ligaments, which are comparatively inactive; and nearly altogether absent in tendons, in which very little organic change occurs after their formation.

Structure.—The walls of the capillaries consist of a fine, transparent, endothelial

layer, composed of cells joined edge to edge by an interstitial cement-substance, and continuous with the endothelial cells which line the arteries and veins. When stained with nitrate of silver the edges which bound the epithelial cells are brought into view (Fig. 668). These cells are of large size and of an irregular polygonal or lanceolate shape, each containing an oval nucleus which may be brought into view by carmine or hæmatoxylin. Between their edges, at various points of their meeting, roundish dark spots are sometimes seen, which have been described as stomata, though they are closed by intercellular substance. They have been believed to be the situation through which the white corpuscles of the blood, when migrating from the blood-vessels, emerge; but this view, though probable, is not universally accepted.

Kolossow, a Russian observer, describes these cells as having a rather more complex structure. He states that they consist of two parts: of hyaline ground-plates, and of a protoplasmic granular part, in which is imbedded the nucleus, on the outside of the ground-plates. The hyaline internal coat of the capillaries does not form a complete membrane, but consists of "plates" which are inelastic, and, though in contact with each other, are not continuous; when, therefore, the capillaries are subjected to intra-vascular pressure, the plates become separated from each other; the protoplasmic portions of the cells, on the other hand, are united together.

In many situations a delicate sheath or envelope of branched nucleated connective-tissue cells is found around the simple capillary tube, particularly in the larger ones; and in other places, especially in the glands, the capillaries are invested with retiform connective tissue.

In the largest capillaries (which ought, perhaps, to be described rather as the smallest arteries or pre-capillaries) there is, outside the epithelial layer, a muscular layer, consisting of contractile fibre-cells, arranged transversely, as in the tunica media of the larger arteries (Fig. 669).

The veins, like the arteries, are composed of three coats—internal, middle, and external; and these coats are, with the necessary modifications, analogous to the coats of the arteries; the internal being the endothelial, the middle the muscular, and the external the connective or areolar (Fig. 670). The main difference be-

FIG. 670.—Transverse section of part of the wall of one of the posterior tibial veins. (After Schäfer).

tween the veins and the arteries is the comparative weakness of the middle coat of the former, and to this is due the fact that the veins do not stand open when divided, as the arteries do, and that they are passive rather than active organs of the circulation.

In the veins immediately above the capillaries the three coats are hardly to be distinguished. The endothelium is supported on an outer membrane separable into two layers, the outer of which is the thicker, and consists of a delicate, nucleated membrane (adventitia), while the inner is composed of a network of longitudinal elastic fibres (media). In the veins next above these in size (one-fifth of a line, according to Kölliker) a muscular layer and a layer of circular fibres can be traced, forming the middle coat, while the elastic and connective elements of the outer coat become more distinctly perceptible. In the middle-sized veins the typical structure of these vessels becomes clear. The endothelium is of the same character

as in the arteries, but its cells are more oval, less fusiform. It is supported by a connective-tissue layer, consisting of a delicate network of branched cells, and external to this is a layer of longitudinal elastic fibres, but seldom any appearance of a fenestrated membrane. This constitutes the *internal coat*. The *middle coat* is composed of a thick layer of connective tissue with elastic fibres, intermixed, in some veins, with a transverse layer of muscular fibres. The white fibrous element is in considerable excess, and the elastic fibres are in much smaller proportion in the veins than in the arteries. The *outer coat* consists of areolar tissue, as in the arteries, with longitudinal elastic fibres. In the largest veins the outer coat is from two to five times thicker than the middle coat, and contains a large number of longitudinal muscular fibres. This is most distinct in the inferior vena cava, and at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the vena portæ, in the splenic, superior mesenteric, external iliac, renal, and azygos veins. In the renal and portal veins it extends through the whole thickness of the outer coat, but in the other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. All the large veins which open into the heart are covered for a short distance with a layer of striped muscular tissue continued on to them from the heart. Muscular tissue is wanting in the veins—(1) of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater of the brain and spinal cord; (3) in the veins of the retina; (4) in the veins of the cancellous tissue of bones; (5) in the venous spaces of the corpora cavernosa. The veins of the above-mentioned parts consist of an internal endothelial lining supported on one or more layers of areolar tissue.

Most veins are provided with valves, which serve to prevent the reflux of the blood. They are formed by a reduplication of the inner coat, strengthened by connective tissue and elastic fibres, and are covered on both surfaces with endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein the cells are arranged transversely; whilst on the other surface, over which the current of blood flows, the cells are arranged vertically in the direction of the current. The valves are semilunar. They are attached by their convex edge to the wall of the vein; the concave margin is free, directed in the course of the venous current, and lies in close apposition with the wall of the vein as long as the current of blood takes its natural course; if, however, any regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the current is interrupted. Most commonly two such valves are found placed opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three and sometimes only one. The wall of the vein on the cardiac side of the point of attachment of each segment of the valve is expanded into a pouch or sinus, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially of the lower extremities, these vessels having to conduct the blood against the force of gravity. They are absent in the very small veins—*i. e.* those less than $\frac{1}{12}$ of an inch in diameter; also in the venæ cavæ, the hepatic veins, portal vein and most of its branches, the renal, uterine, and ovarian veins. A few valves are found in the spermatic veins, and one also at their point of junction with the renal vein and inferior vena cava, respectively. The cerebral and spinal veins, the veins of the cancellated tissue of bone, the pulmonary veins, and the umbilical vein, and its branches, are also destitute of valves. They are occasionally found, few in number, in the venæ azygos and intercostal veins.

The veins are supplied with nutrient vessels, *vasa vasorum*, like the arteries. Nerves also are distributed to them in the same manner as to the arteries, but in much less abundance.

The **lymphatic** vessels, including in this term the lacteal vessels, which are identical in structure with them, are composed of three coats. The *internal* is an

endothelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures sooner than the other coats. It is composed of a layer of elongated endothelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on a single layer of longitudinal elastic fibres. The *middle* coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The *external*, or fibro-areolar, coat consists of filaments of connective tissue, intermixed with smooth muscular fibres, longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighboring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and their structure consists only of a connective-tissue coat, lined by endothelium. The thoracic duct (Fig. 671) is a somewhat more complex structure than the other lymphatics; it presents a distinct subendothelial layer of branched corpuscles, similar to that found in the arteries,

FIG. 671.—Transverse section through the coats of the thoracic duct of man. Magnified 30 times. *a*. Endothelium, striated lamellæ, and inner elastic coat. *b*. Longitudinal connective tissue of the middle coat. *c*. Transverse muscles of the same. *d*. Tunica adventitia, with *e*, the longitudinal muscular fibres.

FIG. 672.—Stroma of serous membranes. 1. Endothelium from the under surface of the *centrum tendineum* of the rabbit. *a*. Stomata. 2. Endothelium of the mediastinum of the dog. *a*. Stomata. 3. Section through the pleura of the same animal. *b*. Free orifices of short lateral passages of the lymph-canals. (Copied from Ludwig, Schweigger-Seidel, and Dybrowsky.)

and in the middle coat is a layer of connective tissue with its fibres arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerve-fibres in the form of a fine plexus of fibrils.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of a thin layer of fibrous tissue, lined on both surfaces by endothelium, which presents the same arrangement upon the two surfaces as was described in connection with the valves of veins. Their form is semilunar; they are attached by their convex edge to the sides of the vessel, the concave edge being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic glands, and they are found more frequently in the lymphatics of the neck and upper extremity than in the lower. The wall of the lymphatics immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Origin of Lymphatics.—The finest visible lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and they consist of a single layer of endothelial plates, with more or less sinuous margins. These ves-

sels commence in an intercommunicating system of clefts or spaces which have no complete endothelial lining in the connective tissue of the different organs. They have been named the *rootlets* of the lymphatics, and are identical with the spaces in which the connective-tissue corpuscles are contained. This then is properly regarded as one method of their commencement, when the lymphatic vessels are apparently continuous with spaces in the connective tissue, and Klein has described and figured a direct communication between these spaces and the lymphatic vessel.¹ But the lymphatics have also other modes of origin, for the intestinal lacteals commence by closed extremities, though some observers believe that the closed extremity is continuous with a minute network contained in the substance of the villus, through which the lacteal is connected with the endothelial cells covering it. Again, it seems now to be conclusively proved that the serous membranes present stomata or openings between the endothelial cells (Fig. 672) by which there is an open communication with the lymphatic system, and through which the lymph is thought to be pumped by the alternate dilatation and contraction of the serous surface, due to the movements of respiration and circulation,² so that the serous and synovial sacs may be regarded, in a certain sense, as large lymph-cavities or sinuses. Von Recklinghausen was the first to observe the passage of milk and other colored fluids through these stomata on the peritoneal surface of the central tendon of the diaphragm. Again, in most glandular structures the lymphatic capillaries have a lacunar origin. Here they begin in irregular clefts or spaces in the tissue of the part; occupying the penetrating connective tissue and surrounding the lacunæ or tubules of the gland, and in many places separating the capillary network from the alveolus or tubule, so that the interchange between the blood and the secreting cells of the part must be carried on through this lymph-space or lacuna. Closely allied to this is the mode of origin of lymphatics in perivascular and perineural spaces. Sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood-capillary. These are known as perivascular lymphatics.

Terminations of Lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points; namely, at the angles of junction of the subclavian and internal jugular veins: on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct. (See description of lymphatics on page 623.)

Lymphatic glands (*conglobate glands*) are small oval or bean-shaped bodies, situated in the course of lymphatic and lacteal vessels, so that the lymph and chyle pass through them on their way to the blood. They generally present on one side a slight depression—the *hilum*—through which the blood-vessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (Fig. 673), a lymphatic gland displays two different structures: an external, of lighter color—the *cortical*; and an internal, darker—the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

Lymphatic glands consist of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculæ*) proceed inward, dividing the gland into open spaces (*alveoli*) freely communicating with each other; (2) a quantity of lymphoid tissue occupying these spaces without completely filling them; (3) a free supply of blood-vessels, which are supported on the trabeculæ; and (4) the *afferent* and *efferent* vessels. Little is known of the nerves, though Kölliker describes some fine nervous filaments passing into the hilum.

¹ *Atlas of Histology*, pl. viii. fig. xiv.

² The resemblance between lymph and serum led Hewson long ago to regard the serous cavities as sacs into which the lymphatics open. Recent microscopic discoveries confirm this opinion in a very interesting manner.

The capsule is composed of a layer of connective tissue, and from its internal surface are given off a number of membranous septa or lamellæ, consisting, in man, of connective tissue, with a small admixture of plain muscle-fibres; but in many of the lower animals composed almost entirely of involuntary muscle. They pass

inward, radiating toward the centre of the gland, for a certain distance; that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. They thus divide the outer part of its interior into a number of oval compartments or *alveoli* (Fig. 673). This is the cortical portion of the gland. After having penetrated into the gland for some distance, these septa break up into a number of smaller trabeculæ, which form flattened bands or cords, interlacing with each other in all directions, forming in the central part of the organ

FIG. 673.—Diagrammatic section of lymphatic gland, showing the course of the lymph.

a number of intercommunicating spaces, also called *alveoli*. This is the medullary portion of the gland, and the spaces or alveoli in it not only freely communicate with each other, but also with the alveoli of the cortical portion. In these alveoli or spaces (Fig. 674) is contained the proper gland-substance or lymphoid tissue.

The gland-pulp does not, however, completely fill the alveolar spaces, but leaves, between its outer margin and the trabeculæ forming the lymphatic channel or space of uniform width throughout. This is termed the *lymph-path* or *lymph-sinus* (Fig. 676). Running across it are a number of trabeculæ of retiform connective tissue, the fibres of which are, for the most part, covered by ramified cells. This tissue

appears to serve the purpose of maintaining the gland-pulp in the centre of the space in its proper position.

On account of the peculiar arrangement of the framework of the organ, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue, being made up of a delicate reticulum of retiform tissue, which is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; in its meshes are closely packed lymph-corpuscles, traversed by a dense plexus of capillary blood-vessels.

The *afferent vessels*, as above stated, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule, open into the lymph-sinuses of the cortical part. In doing this they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. In like manner the *efferent* vessel commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessel thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these, it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum. Hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. This is a matter of considerable importance in connection with the subject of poisoned wounds and the absorption of the poison by the lymphatic system, since by this means septic organisms carried along the lymphatic vessels may be arrested in the lymph-sinuses of the gland tissue, and thus be prevented from entering the general circulation. Many lymph-corpuscles pass with the efferent lymph-stream to join the general blood-stream. The arteries of the gland enter at the hilum, and either pass at once to the gland-pulp, to break up into a capillary plexus, or else run along the trabeculæ, partly to supply them and partly running across the lymph-paths to assist in forming the capillary plexus of the gland-pulp. This plexus traverses the lymphoid tissue, but does not pass into the lymph-sinuses. From it the veins commence, and emerge from the organ at the same place as that at which the artery enters.

THE SKIN AND ITS APPENDAGES.

The skin (Fig. 677) is the principal seat of the sense of touch, and may be regarded as a covering for the protection of the deeper tissues; it plays an important part in the regulation of the body temperature, and is also an excretory and absorbing organ. It consists principally of a layer of vascular tissue, named the *derma*, *corium*, or *cutis vera*, and an external covering of epithelium, termed the *epidermis* or *cuticle*. On the surface of the former layer are the sensitive *papillæ*; and within, or imbedded beneath it, are certain organs with special functions, namely, the *sweat-glands*, *hair-follicles*, and *sebaceous glands*.

The epidermis or cuticle (*scarf-skin*) is non-vascular, and consists of stratified epithelium (Fig. 678). It is accurately moulded on the papillary layer of the derma. It forms a defensive covering to the surface of the true skin, and limits the evaporation of watery vapor from its free surface. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be partly due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layer of cells, called the *horny layer* (*stratum corneum*), may be separated by maceration from the deeper layers, which are called

FIG. 677.—A sectional view of the skin (magnified).

the *rete mucosum* or *stratum Malpighii*, and which consist of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, marking out the surface into a number of spaces of polygonal or lozenge-shaped form. Some of these furrows are large, as opposite the flexures of the joints, and correspond to the folds in the dermis produced by their movements. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles; upon the palmar surface of the hand and fingers and upon the sole of the foot these lines are very distinct and are disposed in curves. They depend upon the large size and peculiar arrangement of the papillæ upon which the epidermis is placed. The deep surface of the epidermis is accurately moulded upon the papillary layer of the dermis, each papilla being invested by its epidermic sheath; so that when this layer is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the elevations in the papillæ, as well as the ridges left in the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

In structure the epidermis consists of several layers of epithelial cells agglutinated together and having a laminated arrangement. These several layers may be described as composed of four different strata from within outward: (1) The *stratum Malpighii*, composed of several layers of epithelial cells, of which the deepest layer is columnar in shape and placed perpendicularly on the surface of the corium,

FIG. 678.—Section of epidermis. (Ranvier.)

their lower ends being denticulate, to fit into corresponding denticulations of the true skin; this deepest layer is sometimes termed the basilar layer or *stratum germinativum*; the succeeding laminae consist of cells of a more rounded or polyhedral form, the contents of which are soft, opaque, granular, and soluble in acetic acid.

FIG. 679.—Microscopic section of skin, showing the epidermis and derma; a hair in its follicle; the erector pili muscle; sebaceous and sudoriferous glands.

They are often marked on their surfaces with ridges and furrows, and are covered with numerous fibrils, which connect the surfaces of the cells: these are known as *prickle cells*. (See page 1075.) They contain numerous epidermic fibrils, which are stained violet with hæmatoxylin and red by carmine, and form threads of union

connecting adjacent cells. Between the cells are fine intercellular clefts, which serve for the passage of lymph and in which lymph-corpuscles or pigment granules may be found. (2) Immediately superficial to these are two or three layers of flattened, spindle-shaped cells, the *stratum granulosum*, which contain granules that become deeply stained in hæmatoxylin; the granules consist of a material named *eleidin*, an intermediate substance in the formation of horn. They are supposed to be cells in a transitional stage between the protoplasmic cells of the stratum Malpighii and the horny cells of the superficial layers. (3) Above this layer the cells become indistinct, and appear, in sections, to form a homogeneous or dimly striated membrane, composed of closely packed scales, in which traces of a flattened nucleus may be found. It is called the *stratum lucidum*. (4) As these cells successively approach the surface by the development of fresh layers from beneath, they assume a flattened form from the evaporation of their fluid contents, and consist of many layers of horny epithelial scales in which no nucleus is discernible, forming the *stratum corneum*. These cells are unaffected by acetic acid, the protoplasm having become changed into horny material or *keratin*. According to Ranvier, they contain granules of a material which has the characters of beeswax. The deepest layer of the stratum Malpighii is separated from the papillæ by an apparently homogeneous basement membrane, which is most distinctly brought into view in specimens prepared with chloride of gold. This, according to Klein, is merely the deepest portion of the epithelium, and is "made up of the basis of the individual cells, which have undergone a chemical and morphological alteration." The black color of the skin in the negro and the tawny color among some of the white races is due to the presence of pigment in the cells of the cuticle. This pigment is more especially distinct in the cells of the deeper layer, or stratum Malpighii, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the color becomes partially lost; the disappearance of the pigment from the superficial layers of the epidermis is, however, difficult to explain.

The *derma*, *corium*, or *cutis vera*, is tough, flexible, and highly elastic, in order to defend the parts beneath from violence.

It varies in thickness, from a quarter of a line to a line and a half, in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than the front, and on the outer than the inner side of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate. The skin is generally thicker in the male than in the female, and in the adult than in the child.

The *corium* consists of felted connective tissue, with a varying amount of elastic fibres and numerous blood-vessels, lymphatics, and nerves. The fibro-areolar tissue forms the framework of the cutis, and is differently arranged in different parts, so that it is usual to describe it as consisting of two layers: the deeper or *reticular* layer, and the superficial or *papillary* layer. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are found; and in the subcutaneous areolar tissue of the scrotum, penis, labia majora of the female, and the nipples. In the latter situation the fibres are arranged in bands, closely reticulated and disposed in superimposed laminæ.

The *reticular* layer consists of strong interlacing fibrous bands, composed chiefly of the white variety of fibrous tissue, but containing, also, some fibres of the yellow elastic tissue, which vary in amount in different parts, and connective-tissue corpuscles, which are often to be found flattened against the white fibrous tissue-bundles. Toward the attached surface the fasciculi are large and coarse, and the areolæ which are left by their interlacement are large, and occupied by adipose tissue and sweat-glands. Below this the elements of the skin become gradually blended with the subcutaneous areolar tissue, which, except in a few situations, contains fat. Toward the free surface the fasciculi are much finer, and their mode of interlacing close and intricate.

The *papillary layer* is situated upon the free surface of the *reticular layer*; it con-

sists of numerous small, highly sensitive, or vascular eminences, the *papillæ*, which rise perpendicularly from its surface. The *papillæ* are conical-shaped eminences, having a round or blunted extremity, occasionally divided into two or more parts and are received into corresponding pits on the under surface of the cuticle. Their average length is about $\frac{1}{100}$ of an inch, and they measure at their base $\frac{1}{250}$ of an inch in diameter. On the general surface of the body, more especially in those parts which are endowed with slight sensibility, they are few in number, short, exceedingly minute, and irregularly scattered over the surface; but in some situations, as upon the palmar surface of the hands and fingers, upon the plantar surface of the feet and toes, and around the nipple, they are long, of large size, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of *papillæ*, and between the two rows the ducts of the sweat-glands pass outward to open on the summit of the ridges. In structure the *papillæ* consist of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue is a capillary loop, and in some, especially in the palms of the hands and fingers, there are tactile corpuscles.

The *arteries* supplying the skin form a network in the subcutaneous tissue, from which branches are given off to supply the sweat-glands, the hair-follicles, and the fat. Other branches are given off which form a plexus immediately beneath the corium; from this fine capillary vessels pass into the *papillæ*, forming, in the smaller *papillæ*, a single capillary loop, but in the larger a more or less convoluted vessel. There are numerous *lymphatics* supplied to the skin which form two networks, superficial and deep, communicating with each other and with those of the subcutaneous tissue by oblique branches. They originate in the cell-spaces of the tissue.

The *nerves* of the skin terminate partly in the epidermis and partly in the cutis vera. The former are prolonged into the epidermis from a dense plexus in the

FIG. 680.—Longitudinal section through human nail and its nail groove (sulcus). (From Böhm and Davidoff's *Histology*).

superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end-bulbs, touch-corpuscles, or Pacinian bodies, in the manner already described; and, in addition to these, a considerable number of fibrils are distributed to the hair-follicles, which are said to entwine the follicle in a circular manner. Other nerve-fibres are supplied to the plain muscular fibres of the hair-follicles (*arrectores pili*) and to the muscular coat of the blood-vessels. These are probably non-medullated fibres.

The **appendages of the skin** are the nails, the hairs, the sudoriferous and sebaceous glands, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

The **nails** (Figs. 680, 681) are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the *root*, into a groove in the skin; the exposed portion is called the

body, and the anterior extremity the *free edge*. The nail has a very firm adhesion to the cutis, being accurately moulded upon its surface, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the *matrix*, because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of longitudinal

FIG. 681.—Transverse section through human nail and its sulcus. (From Böhm and Davidoff's *Histology*.)

ridges, which are very vascular, and the color is seen through the transparent tissue. Behind this, near the root of the nail, the papillæ are small, less vascular, and have no regular arrangement, and here the tissue of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the *lunula* on account of its shape.

The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (*eponychium*) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillæ of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form, and finally become closely compacted together into a firm, dense, horny texture. In *chemical composition* the nails resemble the upper layers of the epidermis. According to Mulder, they contain a somewhat larger proportion of carbon and sulphur.

The hairs are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, and the glans penis. They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length: again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened.

A hair consists of a *root*, the part implanted in the skin; the *shaft* or *stem*, the portion projecting from its surface; and the *point*.

The *root of the hair* presents at its extremity a bulbous enlargement, which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the *hair-follicle* (Fig. 679). When the hair is

of considerable length the follicle extends into the subcutaneous cellular tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hair—to become dilated at its deep extremity, where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands. At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and probably supplied with nervous fibrils. In structure the hair-follicle consists of two coats—an outer or *dermic*, and an inner or *epidermic*.

The *outer* or *dermic* coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (Fig. 682). The most internal, next the cuticular lining of the follicle, consists of a hyaline basement-membrane, having a glassy, transparent appearance, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement-membrane of the surface of the corium. External to this is a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the blood-vessels and nerves.

The *inner* or *epidermic* layer is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the *root-sheath*. It consists of two strata, named respectively the *outer* and *inner root-sheath*; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The *inner* root-sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened, nucleated cells, known as *Huxley's layer*; and finally of a single layer of horny oblong cells without visible nuclei, called *Hentle's layer*.

The hair-follicle contains the root of the hair, which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment-granules, which give rise to the color of the hair. It occasionally happens that these pigment-granules completely fill the cells in the centre of the bulb, which gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The *shaft of the hair* consists of a central pith or medulla, the fibrous part of the hair, and the cortex externally. The medulla occupies the centre of the shaft and ceases toward the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more

FIG. 682.—Transverse section of hair-follicle. 1. Dermic coat of follicle. 2. Epidermic coat or root-sheath. a, Outer layer of dermic coat, with blood-vessels. b, b. Vessels cut across. c. opaque and deeper colored when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air-bubbles. The fibrous portion of the hair constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment-granules in dark hair or minute air-bubbles in white hair. In addition to this there is also a diffused pigment contained in the fibres. The cells which form the cortex of the hair consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed *arrectores pili*. They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action elevate the hair (Fig. 679).¹

The **sebaceous glands** are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face: they are also very numerous around the apertures of the anus, nose, mouth, and external ear; but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary, as a rule, in number from two to five, but in some instances may be as many as twenty. They are composed of a transparent, colorless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their debris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

The **sudoriferous or sweat-glands** are the organs by which a large portion of the aqueous and gaseous materials is excreted by the skin. They are found in almost every part of this structure, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct proceeds upward through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture. The efferent duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, it is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mammillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square

¹ Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.

inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and, supposing the aperture of each gland to represent a surface of $\frac{1}{56}$ of a line in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. In the larger glands this single duct usually divides and subdivides dichotomously; the smaller ducts ultimately terminating in short cæcal pouches, rarely anastomosing. The wall of the duct is thick, the width of the canal rarely exceeding one-third of its diameter. The tube, both in the gland and where it forms the excretory duct, consists of two layers—an outer, formed by fine areolar tissue, and an inner layer of epithelium (Fig. 683). The external or fibro-cellular coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the true skin. The epithelial lining in the distal part of the coiled tube of the gland proper consists of a single layer of cubical epithelium, supported on a basement-membrane, and beneath it, between the epithelium and the fibro-cellular coat, is a layer of longitudinally or obliquely arranged fibres, which are usually regarded as muscular, though the evidence that this is so is not conclusive. In the duct and the proximal part of the coiled tube of the gland proper there are two or more layers of polyhedral cells, lined on their internal surface—*i. e.*, next the lumen of the tube—by a delicate membrane or cuticle, and on their outer surface by a limiting *membrana propria*, but there are no muscular fibres. The epithelium is continuous with the epidermis and with the delicate internal cuticle of the epidermic portion of the tube. When the cuticle is carefully removed from the surface of the cutis, these convoluted tubes of epithelium may be drawn out and form short, thread-like processes on its under surface.

The contents of the smaller sweat-glands are quite fluid; but in the larger glands the contents are semifluid and opaque, and contain a number of colored granules and cells which appear analogous to endothelial cells.

FIG. 683.—Coiled tube of a sweat-gland cut in various directions. *a.* Longitudinal section of the proximal part of the coiled tube. *b.* Transverse section of the same. *c.* Longitudinal section of the distal part of the coiled tube. *d.* Transverse section of the same. (From Klein and Noble Smith's *Atlas of Histology*.)

SEROUS MEMBRANES.

The serous membranes form shut sacs, and may be regarded as lymph-sacs, from which lymphatic vessels arise by stomata or openings between the endothelial cells. (See page 1133.) The sac consists of one portion which is applied to the walls of the cavity which it lines—the *parietal* portion; and another reflected over the surface of the organ or organs contained in the cavity—the *visceral* portion. Sometimes the sac is arranged quite simply, as the *tunica vaginalis testis*; at others with numerous involutions or recesses, as the *peritoneum*, in which, nevertheless, the membrane can always be traced continuously around the whole circumference. The sac is completely closed, so that no communication exists between the serous cavity and the parts in its neighborhood. An apparent exception exists in the *peritoneum* of the female; for the Fallopian tube opens freely into the peritoneal cavity in the dead subject, so that a bristle can be passed from the one into the other.

But this communication is closed during life, except at the moment of the passage of the ovum out of the ovary into the tube, as is proved by the fact that no interchange of fluids ever takes place between the two cavities in dropsy of the peritoneum or in accumulation of fluid in the Fallopian tubes.¹ The serous membrane is often supported by a firm, fibrous layer, as is the case with the pericardium, and such membranes are sometimes spoken of as "fibro-serous."

The various serous membranes are the peritoneum, lining the cavity of the abdomen; the two pleuræ and the pericardium, covering the lungs and heart respectively; and the tunicæ vaginales, surrounding each testicle in the scrotum.² Serous membranes are thin, transparent, glistening structures, lined on their inner surface by a single layer of polygonal or pavement endothelial cells, supported on a matrix of fibrous connective tissue, with networks of fine elastic fibres, in which are contained numerous capillaries and lymphatics. On the surface of the endothelium between the cells numerous apertures or interruptions are to be seen. Some of these are stomata, surrounded by a ring of cubical endothelium (see Fig. 684),

FIG. 684.—Part of peritoneal surface of the central tendon of diaphragm of rabbit, prepared with nitrate of silver. *s.* Stomata. *l.* Lymph-channels. *t.* Tendon-bundles. The stomata are surrounded by germinating epithelial cells. (From *Handbook for the Physiological Laboratory*, Klein.)

and communicating with a lymphatic capillary; others (*pseudostomata*) are mere interruptions in the endothelial layer, and are occupied by processes of the branched connective-tissue corpuscle of the subjacent tissue or by accumulations of the inter-cellular cement-substance.

The amount of fluid contained in these closed sacs is, in most cases, only sufficient to moisten the surface, but not to furnish any appreciable quantity of fluid. When a small quantity can be collected, it is found to resemble lymph, and like that fluid coagulates spontaneously; but when secreted in large quantities, as in dropsy, it is a more watery fluid, but still contains a considerable amount of proteid which is coagulated on boiling.

¹ The communication between the uterine cavity and the peritoneal sac is not only apparent in the dead subject, but is an anatomical fact, which is established by the continuity of its epithelium with that covering the uterus, Fallopian tubes, and fimbriæ.

² The arachnoid membrane, lining the brain and spinal cord, was formerly regarded as a serous membrane, but is now no longer classed with them, as it differs from them in structure, and does not form a shut sac as do the other serous membranes.

SYNOVIAL MEMBRANES.

Synovial membranes, like serous membranes, are connective-tissue membranes placed between two movable tissues, so as to diminish friction, as in movable joints; or between a tendon and a bone, where the former glides over the latter; and between the skin and various subcutaneous bony prominences.

The synovial membranes are composed essentially of connective tissue, with the cells and fibres of that structure, containing numerous vessels and nerves. It was formerly supposed that these membranes were analogous in structure to the serous membranes, and consisted of a layer of flattened cells on a basement-membrane. No such continuous layer, however, exists, although here and there are patches of cells probably epithelial in nature. They are surrounded and held together by an albuminous ground-substance. Long villus-like processes (Fig. 685) are often found projecting from the surface of synovial membranes; they are covered by small rounded cells, and are supposed to extend the surface for the secretion of the fluid which moistens the membranes, and which is named *synovia*. It is a rich lymph, plus a mucin-like substance, and to the latter constituent it owes its viscosity. A further description of the synovial membranes will be found in the descriptive anatomy of the joints.

FIG. 685.—Villus of synovial membrane. (After Hammar).

MUCOUS MEMBRANE.

Mucous membranes line all those passages by which the internal parts communicate with the exterior, and are continuous with the skin at the various orifices of the surface of the body. They are soft and velvety, and very vascular, and their surface is coated over by their secretion, *mucus*, which is of a tenacious consistence, and serves to protect them from the foreign substances introduced into the body with which they are brought in contact.

They are described as lining the two tracts—the gastro-pulmonary and the genito-urinary; and all, or almost all, mucous membranes may be classed as belonging to and continuous with the one or the other of these tracts.

The deep surfaces of these membranes are attached to the parts which they line by means of connective tissue, which is sometimes very abundant, forming a loose and lax bed, so as to allow considerable movement of the opposed surfaces on each other. It is then termed the *submucous tissue*. At other times it is exceedingly scanty, and the membrane is closely connected to the tissue beneath; sometimes, for example, to muscle, as in the tongue; sometimes to cartilage, as in the larynx; and sometimes to bone, as in the nasal fossæ and sinuses of the skull.

In structure a mucous membrane is composed of *corium* and *epithelium*. The epithelium is of various forms, including the squamous, columnar, and ciliated, and is often arranged in several layers. This epithelial layer is supported by the corium, which is analogous to the dermis of the skin, and consists of connective tissue, either simply areolar or containing a greater or less quantity of lymphoid

tissue. This tissue is usually covered on its external surface by a transparent basement-membrane generally composed of clear flattened cells, placed edge to edge; on this the epithelium rests. It is only in some situations that the basement-membrane can be demonstrated. The corium is an exceedingly vascular membrane, containing a dense network of capillaries, which lie immediately beneath the epithelium, and are derived from small arteries in the submucous tissue.

The fibro-vascular layer of the corium contains, besides the areolar tissue and vessels, unstriated muscle-cells, which form in many situations a definite layer, called the *muscularis mucosa*. These are situated in the deepest part of the membrane, and are plentifully supplied with nerves. Other nerves pass to the epithelium and terminate between the cells. Lymphatic vessels are found in great abundance, commencing either by caecal extremities or in networks, and communicating with plexuses in the submucous tissue.

Imbedded in the mucous membrane are found numerous glands, and projecting from it are processes (villi and papillæ) analogous to the papillæ of the skin. These glands and processes, however, exist only at certain parts, and they have been described for the sake of convenience, and with the parts as they occurred.

SECRETING GLANDS.

The **secreting glands** are organs whose cells produce, by the metabolism of their protoplasm, certain substances, called "secretions," of a more or less definite composition; the material for the secretion being primarily selected from the blood. The essential parts, therefore, of a secreting gland are *cells*, which have the power of extracting from the blood certain matters, and in some cases converting them into new chemical compounds; and *blood-vessels*, by which the blood is brought into close relationship with these cells. The general arrangement in all secreting structures—that is to say, not only in secreting glands, but also in secreting membranes—is that the cells are arranged on one surface of an extravascular basement-membrane, which supports them, and a minute plexus of capillary vessels ramifies on the other surface of the membrane. The cells then extract from the blood certain constituents which pass through the membrane into the cells, where they are prepared and elaborated. The basement-membrane does not, however, always exist, and any free surface would appear to answer the same purpose in some cases.

By the various modifications of this secreting surface the different glands are formed. This is generally effected by an invagination of the membrane in different ways, the object being to increase the extent of secreting surface within a given bulk.

In the simplest form a single invagination takes place, constituting a *simple gland*; this may be either in the form of an open tube (Fig. 686, A), or the walls of the tube may be dilated so as to form a saccule (Fig. 686, B). These are named the *simple tubular* or *saccular glands*. Or, instead of a short tube, the invagination may be lengthened to a considerable extent, and then coiled up to occupy less space. This constitutes the *simple convoluted tubular gland*, an example of which may be seen in the sweat-glands of the skin (Fig. 686, C).

If, instead of a single invagination, secondary invaginations take place from the primary one, as in Fig. 686, D and E, the gland is then termed a compound one. These secondary invaginations may assume either a saccular or tubular form, and so constitute the two subdivisions—the *compound saccular* or *racemose gland*, and the *compound tubular*. The racemose gland in its simplest form consists of a primary invagination which forms a sort of duct, upon the extremity of which are found a number of secondary invaginations called saccules or alveoli, as in Brunner's glands (Fig. 686, D). But, again, in other instances, the duct, instead of being simple, may divide into branches, and these again into other branches, and so on; each ultimate ramification terminating in a dilated cluster of saccules, and thus we may have the secreting surface almost indefinitely extended, as in the salivary

glands (Fig. 686, E). In the *compound tubular* glands the division of the primary duct takes place in the same way as in the racemose glands, but the branches retain their tubular form, and do not terminate in saccular recesses, but become greatly lengthened out (Fig. 686, F). The best example of this form of gland is to

FIG. 686.—Diagrammatic plan of varieties of secreting glands. A. Simple gland. B. Sacculated simple gland. C. Simple convoluted tubular gland. D, E. Racemose gland. F. Compound tubular gland.

be found in the kidney. All these varieties of glands are produced by a more or less complicated invagination of a secreting membrane, and they are all identical in structure; that is to say, the saccules or tubes, as the case may be, are lined with cells, generally spheroidal or columnar in figure, and on their outer surface is an intimate plexus of capillary vessels. The secretion, whatever it may be, is eliminated by the cells from the blood, and is poured into the saccule or tube, and so finds its way out through the primary invagination on to the free surface of the secreting membrane. In addition, however, to these glands, which are formed by an *invagination* of the secreting membrane, there are some few others which are formed by a *protrusion* of the same structure, as in the vascular fringes of synovial membranes. This form of secreting structure is not nearly so frequently met with.

EMBRYOLOGY.

THE OVUM.

THE whole body is developed out of the ovum or female element (Figs. 687 and 688) after it has been fertilized by the spermatozoön or male element. The ovum is a simple nucleated cell, and all the complicated changes by which the various intricate organs of the body are formed from it may be reduced to two general processes, viz., the *segmentation* or *cleavage* of cells, and their *differentiation*. The former process consists in the division of the nucleus and the surrounding cell-substance, whereby the original cell is represented by two. The differentiation of cells is a term used to describe that unknown power or tendency impressed on cells, apparently identical in structure, whereby they grow into different forms; so that (to take one of the first phenomena which occurs in the growth of the embryo) the indifferent cells of the vascular area are differentiated, some of them into blood-globules, others into the solid tissue which forms the blood-vessels. The extreme complexity of the process of development renders it at all times difficult to describe intelligibly, and still more so in a work like this, where adequate space and illustration can hardly be afforded, having respect to the main purpose of the work, and therefore an outline of the principal facts only will be given. Many of the statements which are accepted in human embryology are made on the strength of what has been observed to occur in the lower animals, and their existence in the human subject is merely a matter of inference. Within recent years, however, much has been added to our knowledge of the development of the human embryo, and this more especially by the important researches of Professor His and others.

FIG. 687.—Human ovum from a middle-sized follicle. Magnified 350 times. *a.* Zona pellucida or zona radiata. *b.* External border of the yolk and internal border of the vitelline membrane. *c.* Germinal vesicle and germinal spot.

The ovum is a small spheroidal body situated in the immature Graafian follicle near its centre, but in the mature one in contact with the *membrana granulosa*,¹ at that part of the follicle which projects from the surface of the ovary. The cells of the *membrana granulosa* are accumulated round the ovum in greater number than at any other part of the follicle, forming a kind of granular zone, the *discus proligerus*.

The human ovum (Fig. 687) is extremely minute, measuring from $\frac{1}{150}$ to $\frac{1}{125}$ of an inch in diameter. It is a cell consisting externally of a transparent striated envelope, the *zona pellucida*, *zona radiata*, or *vitelline membrane*. The extra-nuclear protoplasm contained within the *zona pellucida* is known as the *cytoplasm*; it is a sponge-like material, containing in its meshes numerous large fatty and albuminous granules, which constitute the *yolk* or *vitellus*; in the neighborhood of the nucleus, however, these granules are comparatively few in number. The nucleus is a large spherical body, which is known by the name of the *germinal vesicle*, and resembles in structure the nucleus of an ordinary cell. Within it there is generally one nucleolus, which is large and well marked, and is known as the *germinal spot*. The *zona pellucida* is believed to be pierced by numerous pores which are probably channels of nutrition and which give it

¹ See the description of the ovary at a future page.

the appearance of being radially striated, while in some animals (*e.g.*, insects) it presents a small perforation or hole, which is known by the name of the *micropyle*, and is believed to be the means by which the spermatozoa enter the ovum.

The phenomena attending the discharge of the ova from the Graafian follicles, since they belong as much or more to the ordinary function of the ovary than to the general subject of the development of the body, are described with the anatomy of the ovaries on a subsequent page.

FIG. 688.—Ovum of rabbit. Highly magnified. (After Waldeyer.)

Maturation of the Ovum previous to Fertilization.—Either before or immediately after its escape from the Graafian follicle, important changes take place in the nucleus of the ovum, which result in its partial disappearance and in the formation and extrusion from the yolk of two peculiar bodies, the *polar bodies* or *polar globules* of Robin. These changes constitute what is termed the *maturation of the ovum*, and are preparatory to its being fertilized by the male element or spermatozoon. The nucleus approaches the periphery of the ovum and undergoes the changes associated with karyokinesis; it then divides into two, and the upper daughter nucleus, with a thin investment of protoplasm, becomes extruded as the first polar body into a space between the yolk and the vitelline membrane, which has been formed in consequence of a contraction or shrinking of the yolk. The lower daughter nucleus undergoes the same process of division, and forms a second polar body, which is in like manner extruded (Fig. 689). The greater part (three-fourths) of the original nucleus is therefore expelled from the yolk in the form of the two polar bodies, and the remaining fourth, which is now called the *female pronucleus*, recedes toward the centre of the ovum. The shrinking of the vitellus still continues, and a fluid—the *perivitelline* fluid—collects in the space between it and the zona pellucida; in it, spermatozoa, which have passed through the zona pellucida, may sometimes be seen.

Although the process of maturation has been closely followed in many of the lower animals, it has not yet been successfully demonstrated in mammals.

It is interesting to note that a similar nuclear reduction occurs in connection with the development of spermatozoa. In the germinal ridge, which is to become the future testicle, certain cells, identical with primitive ova, are found. These are termed *spermatoblasts*, and they become enlarged to form what are called *spermatocytes*, while each spermatocyte ultimately divides into four *spermatids*. The spermatids become changed, without further subdivision, into spermatozoa, and

hence the fully developed spermatozoon contains only one-fourth of the nucleus of the original spermatocyte. The matured ovum and the spermatozoon may therefore be looked upon as of the same morphological value.

FIG. 689.—Formation of polar bodies in *Asterias glacialis*. (Hertwig.) In I. the polar spindle (*sp*) has advanced to the surface of the egg. In II. a small elevation (*rk*) is formed which receives a half of the spindle. In III. the elevation is constricted off, forming a polar body (*rk'*). Out of the remaining half of the previous spindle a second complete spindle (*sp*) has arisen. In IV. is seen a second elevation, which in V. has become constricted off as the second polar body. Out of the remainder of the spindle (IV.) is developed the female pronucleus.

FERTILIZATION AND SEGMENTATION OF THE OVUM.

The first changes in the ovum which take place at the time of conception are as follows:

1. **Impregnation.**—One, or perhaps more, spermatozoa penetrate the zona pellucida and are contained in the perivitelline fluid. A single spermatozoon,

FIG. 690.—Fertilization of the ovum of an echinoderm. *s*. Spermatozoon. *m. pr.* Male pronucleus. *f. pr.* Female pronucleus. 1. Accession of a spermatozoon to the periphery of the vitellus. 2. Its penetration. 3. Transformation of the head of the spermatozoon into the male pronucleus. 4, 5. Blending of the male and female pronuclei. (From Quain's *Anatomy*, Selenka.)

more advanced than the rest, becomes buried in the yolk, the tail disappears, and the head constitutes the *male pronucleus*. This gradually approaches the female pronucleus, and ultimately the two pronuclei come into contact and fuse to form a new nucleus, containing both male and female elements, and named the *segmentation* or *cleavage* nucleus, and the whole cell thus modified is called the *blastosphere* (Fig. 690). It seems as if this normally occurs in the Fallopian tube,¹ but it is possible that it sometimes takes place before the ovum has entered

¹ Many physiologists, as Bischoff and Dr. M. Barry, taught that the ovum is fecundated in the ovary, but the reasoning of Dr. Allen Thomson appears very cogent in proving that the usual spot at which the spermatozoa meet the ovum is in the tube, down which it slowly travels to the uterus, in its course becoming surrounded by an albuminous envelope derived from the walls of the tube.

the tube, or even after it has passed through the tube and reached the cavity of the uterus; abnormally it may take place in the peritoneal cavity.

2. **Segmentation.**—The first result of fertilization is a cleavage or subdivision of the ovum, which is first cleft into two masses, the segmentation nucleus having

FIG. 691.—First stages of segmentation of a mammalian ovum: semi-diagrammatic. (From a drawing by Allen Thomson.) *z.p.* Zona pellucida. *p.gl.* Polar globules. *u.* Epiblastic cell. *l.* Hypoblastic cell. *a.* Division into two spheres. *b.* Stage of four spheres. *c.* Eight spheres, the epiblastic cells partially enclosing the hypoblastic cells. *d, e.* Succeeding stages of segmentation, showing the more rapid division of the epiblastic cells and the enclosure of the hypoblastic cells by them.

previously split up into two; so that it now consists of two separate masses of protoplasm, each containing a nucleus, and situated within the original zona pellucida, which takes no part in this process of division. Then, each of these

FIG. 692.—Ovum of the rabbit at the end of the process of segmentation. *oc.* Primitive epiblast. *ic.* Primitive hypoblast. *bp.* Place where the epiblast has not yet grown over the hypoblast. (From Balfour, after Edvan Beneden.)

two divides in like manner, and thus four are formed, and so on, until at length a mulberry-like agglomeration of nucleated masses of protoplasm results (Fig. 691). These masses are sometimes termed *vitelline spheres*.

The manner in which segmentation occurs is somewhat peculiar. The two cells resulting from the first cleavage are of unequal size. One, which for the sake of distinction may be called the *upper*, is slightly larger and paler than the other, or *lower*. After they have subdivided three or four times the rate of cleavage in the cells derived from the upper becomes more rapid than that in the cells derived from the lower. In addition, the upper cells have a tendency to spread over and

enclose the lower cells, so that by the ninth or tenth division there is an external layer of pale cells enclosing a mass of slightly smaller, more opaque cells, which, in consequence of their diminished rate of cleavage, are fewer in number (Fig.

FIG. 693.—Blastodermic vesicle of *Vespertilio murinus*. (After Van Beneden.) (Reduced from a drawing in the *Anatomischer Anzeiger*, xvi. Band, Sept. 8, 1899.)

692). Fluid collects between the two sets of cells, except at one part, termed the *embryonal pole*, so that a vesicle, the *blastodermic vesicle*, is formed. This vesicle consists of an outer layer of cells, termed Rauber's layer, derived from the

FIG. 694.—Section through embryonic area of *Vespertilio murinus*. (After Van Beneden.) (Reduced from a drawing in the *Anatomischer Anzeiger*, xvi. Band, Sept. 8, 1899.)

subdivision of the primary upper cell, enclosing at the embryonal area an inner mass of cells (Fig. 693) resulting from the cleavage of the primary lower cell. Rauber's layer takes no share in the formation of the embryo proper, which is entirely developed from the inner mass of cells. The deepest cells of this mass

FIG. 695.—Section through embryonic area of *Vespertilio murinus* (after Van Beneden), to show the formation of the amniotic cavity. (Reduced from a drawing in the *Anatomischer Anzeiger*, xvi. Band, Sept. 8, 1899.)

become differentiated as a layer of flattened cells, termed the *hypoblast*, which spreads outward beneath Rauber's layer. The latter, by subdivision of the cells of its upper hemisphere, is differentiated into two strata, the outer of which becomes rapidly thickened and forms a *plasmodioblast* (*i. e.*, a mass of protoplasm containing numerous nuclei, but not subdivided into individual cells by means of

cell-walls); the inner layer assumes the form of a prismatic epithelium, and is named the *cytoblast* (Fig. 695). These two layers form the *ectoplacenta* or *chorion*, and entirely replace the lining epithelium of the uterus where the blastodermic vesicle comes into contact with it. According to Van Beneden, the cells of the inner mass partly undergo atrophy (Fig. 694), giving rise to a cavity, limited above by the cytoblast and below by a layer of cells, which constitutes the primitive upper layer of the embryo, the *epiblast* or *ectoderm*, and which is continuous peripherally with the cytoblast. The cavity thus formed is the *primitive amniotic cavity*, and becomes the permanent amniotic cavity in man and monkeys, and in some of the bats (Fig. 695). It will thus be seen that from the inner mass of cells two layers are formed—an outer of prismatic cells, the epiblast or ectoderm, and an inner of flattened cells, the hypoblast or entoderm—and this double layer constitutes the *blastodermic membrane*, which at this stage is *bilaminar*.¹

FIG. 696.—Embryo of a rabbit of eight days. (After Kölliker.) *arg.* Embryonic area. *pr.* Primitive streak.

from there gradually extends forward. The epiblast covering the primitive streak becomes indented by a groove, the *primitive groove*, the anterior end of which

communicates through a canal with the yolk-sac, forming what is termed the *blastopore*. The primitive streak results from a multiplication of the cells of the epiblast, so that it becomes thickened and grows downward toward the hypoblast, which also undergoes proliferation. Together they form a thick cellular column, in which it is no longer possible to distinguish the epiblastic from the hypoblastic cells. From the sides of this column a layer of cells grows out between the epiblast and hypoblast, having been derived partly from both; this layer constitutes the *mesoblast* or *mesoderm*.

In this way the blastodermic membrane comes to consist of three layers, and is now known as the *trilaminar blastoderm*. Each layer has distinctive characters, the outer and inner presenting the appearance of epithelial cells, while the middle consists of a mass of

branched cells without any definite arrangement. The external is termed the *epiblast*, or *ectoderm*; the internal the *hypoblast*, or *entoderm*; and the middle, the *mesoblast*, or *mesoderm* (Fig. 698).

¹ Consult, in this connection, articles by Van Beneden and Kollmann, *Anatomischer Anzeiger*, 1899 and 1900.

FIG. 697.—Embryonic area of the ovum of a rabbit at the seventh day. *ag.* Embryonic area. *o o.* Region of the blastodermic vesicle immediately surrounding the embryonic area. *pr.* Primitive streak. *rf.* Medullary groove. (From Kölliker.)

The *epiblast* consists of a layer of columnar epithelial cells, which, however, are somewhat flattened toward the circumference of the germinal disk. It forms the whole of the nervous system (central and peripheral), the epidermis of the skin, the hairs and nails, the lining cells of the sebaceous, sweat, and mammary glands, the enamel of the teeth, and the epithelial lining of the nasal passage and of portions of the mouth and pharynx.

The *hypoblast* consists, at first, of flattened epithelial cells, which subsequently become columnar and even larger than those of the epiblast. It forms the epithelial lining of the whole of the alimentary canal except the anus and part of the mouth (which are developed from involutions of the epiblast), the epithelial lining of all the glands opening into the alimentary canal, the epithelium of the Eustachian tube and tympanic cavity, and of the trachea, bronchial tubes, and air-sacs of the lungs, the epithelium of the bladder and urethra, and also that which lines the follicles of the thyroid and thymus glands. The endothelial lining of the heart,

blood-vessels, and serous cavities is also of hypoblastic origin, while recent observations tend to show that the primitive red blood-cells are derived from the same source.

The *mesoblast* consists of loosely arranged branched cells, which are surrounded by a considerable amount of intercellular fluid, and which therefore may be considered as resembling embryonic connective tissue. All the other tissues of the embryo are developed from it, including the extra-endothelial portion of the walls of the blood-vessels, the skeleton and voluntary muscles, the connective tissues, the spleen, the generative and urinary organs (except the epithelium of the bladder and urethra), and the involuntary muscles.

FIRST RUDIMENTS OF THE EMBRYO.

The *primitive streak* alluded to above is a very transitory structure, which merely marks the direction of the embryonic axis, the embryo proper being developed immediately in front of it in the following manner (Figs. 697 and 701):

First, two longitudinal ridges, caused by a looping or folding up of the epiblast, appear, one on either side of the middle line. These commence in the anterior part of the area germinativa, where they are united, and extend backward, one on either side of the primitive streak, gradually enclosing it, and thus converting the blastopore into the *neurenteric canal*. This folding up of the epiblast gives rise to a longitudinal groove, the *medullary* or *neural groove* (Figs. 697 and 698), in consequence of the manner in which the cells of the epiblast are heaped up into two longitudinal ridges, with a furrow between them so that the sides and floor of the groove are formed of epiblastic cells (Fig. 698). The mesoblast fills up the space between the epiblast and hypoblast, so that the sides of the groove are occupied by a longitudinal thickening of mesoblast; the two longitudinal thicken-

ings of mesoblast being at first separated at the bottom of the groove by the junction of the epiblast and hypoblast (Fig. 698). The groove becomes deeper in consequence of the further growing up of the cells to form the ridge on either side. In this way the ridges eventually become two plates, the *laminae dorsales* or *medullary plates*, which finally coalesce and form a closed tube, the *neural canal*, which is lined and covered by epiblast (Figs. 699 and 700). These lining and covering layers of epiblast are at first in contact with one another, but eventually become separated by mesoblast which grows up between them. The coalescence of the medullary plates first takes place in the region of the future hind-brain of the embryo, and then extends toward the cephalic and caudal ends. The posterior extremity presents a rhomboidal appearance before the *laminae* close; this has been termed the *sinus rhomboidalis* (Fig. 701). The epiblast which lines the neural canal is developed into the nervous centres, that which covers the canal into the epidermis of the back and head. The cephalic extremity of the neural canal is soon seen to be more dilated than the rest, and to present restrictions dividing it imperfectly into three chambers: the brain is developed from this dilated portion; the spinal cord takes its origin from the remainder of the tube. Below the neural canal, in front of the internal opening of the blastopore, a longitudinal groove forms in the hypoblast; this groove becomes closed off from the roof of the future enteron and forms a rod of cells which lies between the hypoblast and the neural canal. This rod of cells is known as the *notochord* or *chorda dorsalis*, and when fully developed is composed of clear epithelium-like cells enclosed in a homogeneous sheath

FIG. 699. — Transverse sections through the embryo chick, before and some time after the closure of the medullary canal, to show the upward and downward inflections of the blastoderm. (After Remak.) (Fig. 700). It is essentially an embryonic structure, though traces of it remain in the centre of the intervertebral disks throughout life. The collection of mesoblastic cells, which forms a thick longitudinal column on either side of the neural canal, is termed the *paraxial* mesoblast, as distinguished from the outer or *lateral* part of the meso-

FIG. 700.—Section across the dorsal part of a chick embryo of forty-five hours' incubation. (Balfour.)

blast layer. The paraxial mesoblast undergoes a series of transverse segmentations and becomes converted into a row of well-defined, dark, square segments or masses, the *protovertebrae* or *mesoblastic somites*, separated by clear, transverse intervals (Figs. 700 and 701). They first make their appearance in the region which afterward becomes the neck, and from there extend backward along the

entire length of the trunk. These bodies, as will be explained hereafter, are not the representatives of the permanent vertebræ, but are differentiated, partly into the vertebræ and partly into the muscles and true skin. On either side of the protovertebræ the lateral mesoblast splits into two layers; the upper becomes applied to the epiblast, forming with it the *somatopleure* or body wall, while the lower becomes attached to the hypoblast and with it forms the *splanchnopleure* or wall of the alimentary tube (Fig. 699). The space between them is the *cælum* or

FIG. 701.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect; $\times 30$. (From Duval's *Atlas d'Embryologie*.)

pleuro-peritoneal cavity (Fig. 700). While the parietes of the body are still unclosed, this cavity is continuous with the space between the amnion and chorion, as seen in Fig. 705. The embryo, which at first seems to be a mere streak, extends longitudinally and laterally. As it grows forward the cephalic end becomes

remarkably curved on itself (cephalic flexure), and a smaller but similar folding-over takes place at its hinder end (caudal flexure). At the same time the sides of the embryo, formed by the somatopleure, grow and curve ventrally toward each other, so that the embryo at this stage is aptly compared to a canoe turned over, and becomes marked off from the general blastoderm by a *limiting sulcus*. In consequence of this incurving of the embryo, both in an antero-posterior and a lateral direction, the blastodermic vesicle becomes nipped by the somatopleure and resembles an hour-glass with two unequal parts. The smaller portion is enclosed within the body of the embryo, and constitutes the *enteron* or primitive alimentary canal, while the larger portion, left outside the embryo, is termed the *yolk-sac* or *umbilical vesicle*. These two parts of the original blastodermic vesicle communicate through the constricted portion, which is the site of the future umbilicus, and,

FIG. 703.—Diagrammatic section through the ovum of a mammal in the long axis of the embryo. *e*. The cranio-vertebral axis. *i, i*. when the body cavity is ultimately closed at the umbilicus, the constriction is narrowed to form a small duct, the *omphalo-mesenteric* or *vitelline duct* (Figs. 702, 703, and 705). The cephalic part of the primitive alimentary canal is named the *fore-gut*, the caudal portion the *hind-gut*, while the intermediate portion which communicates directly with the yolk-sac, is termed the *mid-gut*. The yolk-sac is of small importance and very temporary duration in the human subject. It is for the purpose of supplying nutrition to the embryo during the very earliest period of its existence. In the oviparous animals, however, where no supply of nourishment can be obtained from the mother, since the egg is entirely separated from her, the yolk-sac is large and of great importance, as it supplies nutrition to the chick during the whole of foetation. Vessels developed in the mesoblast soon cover the yolk-sac, forming the *vascular area*; these are named the *omphalo-mesenteric* vessels, and are two in number (Fig. 704). They appear to absorb the fluid of the yolk-sac which, when the fluid has disappeared, dries up and has no further function. The activity of the yolk-sac ceases about the fifth or sixth week, at the same time that the allantois, which is the great bond of vascular connection between the embryo and the uterine tissues, is formed. The yolk-sac remains visible, however, up to the fourth or fifth month, with its pedicle and the omphalo-

mesenteric vessels. The latter vessels become atrophied as the functional activity of the body with which they are connected ceases.

So far we have traced: (1) the segmentation or cleavage of the ovum and the formation of a blastodermic vesicle, consisting of (a) an external envelope, and (b) an internal mass of cells applied to it at the embryonal pole, but separated elsewhere by an albuminous fluid. (2) The separation of the hypoblast from the inner surface of this internal mass and its extension as a lining to the external envelope. (3) The development of the epiblast, also from the internal mass of cells, absorption taking place between it and the external layer to form a cavity, the primitive amniotic cavity. (4) The formation of an oval-shaped disk, the germinal disk, and the appearance of the primitive streak at its posterior end.

FIG. 704.—Magnified view of the human embryo of four weeks, with the membranes opened. (From Leishman, after Coste.) *y*. (5) The development of the mesoblast from the primitive streak and its extension between the epiblast and mesoblast. (6) The formation of the "neural groove" in front of this primitive streak, caused by the growing-up of the epiblast on either side of it, so as to form two longitudinal ridges, called the "laminæ dorsales." (7) The increase and incurvation of these laminæ dorsales, until they meet dorsally and enclose the "neural canal," from the epiblastic lining of which the nervous centres are developed. (8) The formation, from the hypoblast immediately under the canal, of a continuous rod of cells, the "cauda dorsalis" or "notochord." (9) The formation, from the paraxial mesoblast, on either side of the notochord, of a number of square segments, the "protovertebræ" or "mesoblastic somites." (10) The splitting of the lateral mesoblast into two layers

to form the "somatopleure" and "splanchnopleure," the space between the two constituting the "cœlum" or "pleuro-peritoneal cavity." (11) The curving of the embryo on itself, both longitudinally and laterally, so as to be comparable to a canoe, part of the blastodermic vesicle being enclosed within the embryo to form the "primitive alimentary tube," part being left outside as the "yolk-sac," the two communicating by a duct, the "omphalo-mesenteric" duct. The yolk-sac provides nutrition to the embryo through the omphalo-mesenteric vessels until such time as the placenta is formed.

FORMATION OF MEMBRANES.

In order to have a clear understanding of the manner in which the embryo is developed, it is necessary at this stage to describe the development of the foetal membranes.

The membranes investing the foetus are the amnion, the chorion, and the decidua. The first two are developed from foetal structures, and are proper to the foetus; the last is formed in the uterus, and is derived from the maternal structures.

The Amnion.—The amnion is the innermost of the membranes which surround the embryo. It is at first of small size, but increases considerably toward the middle of pregnancy, as the foetus acquires the power of independent movement. It exists only in reptiles, birds, and mammals, which are hence called "Amniota," but is absent in amphibia and fishes. In man, monkeys, and some of the bats, the primitive amniotic cavity, already described on page 1154, persists. In reptiles, birds, and certain mammals the amnion is formed in the following manner. At or

FIG. 705.—Diagram of a transverse section of a mammalian embryo, showing the mode of formation of the amnion. The amniotic folds have nearly united in the middle line. (From Quain's *Anatomy*, vol. i. pt. i. 1890.) Epiblast, ----; mesoblast, -----; hypoblast and notochord, continuous line.

near the extremities of the incurved foetus—that is to say, at the point of constriction of the blastodermic vesicle where the primitive alimentary canal of the embryo joins the yolk-sac—a reflection or folding backward of the somatopleure, which has become separated from the splanchnopleure by the formation of the pleuro-peritoneal cavity, takes place (Fig. 702, 2, 3). This fold commences first at the cephalic extremity, and subsequently at the caudal end and sides, and deepens more and more, in consequence of the sinking of the embryo into the blastodermic vesicle, until, gradually approaching, the different parts meet on the dorsal aspect of the embryo (Figs. 702, 10, and 705). After they come in contact

they fuse together, and the septum between them disappears; so that the inner layer of the cephalic fold becomes continuous with the inner layer of the caudal and lateral folds, and the outer with the outer. Thus we have two membranes, one formed by the inner layer of the fold—the *true amnion*—which encloses a space over the back of the embryo—the *amniotic cavity* (Fig. 702, 4, 5)—containing a clear fluid, the *liquor amnii*. The other, the outer layer of the fold—the *false amnion*—lines the internal surface of the original zona pellucida. Between the two is an interval, which of course communicates with the pleuro-peritoneal cavity until the body-walls of the embryo have coalesced at the umbilicus. Then the amniotic fold is carried downward, and encloses the umbilical cord, by which the foetus is attached to the placenta. The true amnion—or, as it is usually called, the amnion—is formed of two layers, inner and outer, derived respectively from the epiblast and from the parietal layer of the mesoblast.

The amnion is at first in close contact with the surface of the body of the embryo, but about the fourth or fifth week fluid begins to accumulate, and thus separates the two. The quantity of fluid steadily increases up to about the sixth month of pregnancy, after which it diminishes somewhat. The use of the liquor amnii is believed to be chiefly to allow of the movements of the foetus in the later stages of pregnancy, though it no doubt serves other purposes. It contains about 1 per cent. of solid matter, chiefly albumen, with traces of urea, the latter probably derived from the urinary secretion of the foetus.

FIG. 706.—Transverse section through the dorsal region of an embryo chick, end of third day. (From Foster and Balfour.) *Am*. Amnion. *mp*. Muscle-plate. *cv*. Cardinal vein. *Ao*. Hypoblast. The section passes through the place where the alimentary canal (*hy*) communicates with the yolk-sac. *Sp*. Splanchnopleure.

The Chorion.—The chorion takes its origin, as has already been seen (page 1154), from the external covering of the blastodermic, vesicle the cells of the decidua or uterine mucous membrane contributing no elements to it. From its outer surface numerous finger-like processes, termed the *villi of the chorion*, project. These increase rapidly in size and at the same time undergo great ramification; hence they were likened by Dalton to tufts of seaweed (Figs. 705 and 708). They invade

the decidua of the uterus and probably absorb from it nutritive materials for the growth of the embryo: they can be forcibly withdrawn from the decidua until the third month of pregnancy. Until about the end of the second month the villi cover the whole surface of the chorion and are of an almost uniform size, but after this they develop unequally. On that part which invades the decidua serotina they increase greatly in size and complexity, and constitute the *chorion frondosum*, which becomes the fœtal part of the placenta (Fig. 708). Over the remainder of the chorion they undergo atrophy, so that by the fourth month hardly any trace of them is left, and hence this part becomes smooth, and is therefore named the *chorion læve*. The chorionic villi are at first non-vascular, but subsequently they become vascularized by the growth into them of the allantoic mesoblast, which carries to them the branches of the allantoic arteries.

The Allantois.—The allantois grows outward as a hollow bud from the hind gut, and is therefore lined by hypoblast and covered by mesoblast (Figs. 702, 4, 5, and 703). It is projected into the space between the amnion and the chorion, and in its mesoblast are carried a pair of arteries, the *allantoic* or *umbilical arteries*, which are continued from the two primary aortæ. The allantoic mesoblast gradually spreads out on the inner surface of the chorion, and, invading the chorionic villi, supplies them with blood-vessels. In this way the allantois becomes the chief agent of the fœtal circulation, since it carries the vessels which convey the blood of the embryo to the chorion, where it is exposed to the influence of the maternal blood circulating in the decidua; from the maternal blood it imbibes the materials of nutrition and to it it gives up effete materials, the removal of which is necessary for the purification of the fœtal blood. In some animals the allantois is a hollow projection, and is usually styled the *allantoic vesicle*; but in most mammals, and especially in man, the external or mesoblastic element undergoes great development, while the internal or hypoblastic element undergoes little increase beyond the body of the embryo, so that it is very doubtful whether any cavity exists in the allantois beyond the limits of the umbilicus, or whether it does not rather consist of a solid mass of material derived from the mesoblastic tissue.¹ The proximal part of the allantoic vesicle within the body-cavity is eventually destined to form the bladder, while the remainder forms an impervious cord, the *urachus*, stretching from the summit of the bladder to the umbilicus. The part of the allantois external to the fœtus forms the umbilical cord, by which the fœtus is connected with the placenta.

The Decidua.—The growth of the chorion and placenta can be understood only by tracing the formation of the decidua.

The decidua is formed from the uterine mucous membrane before the fertilized ovum reaches the cavity of the uterus. The mucous membrane becomes vascular and tumid, its glands are greatly elongated, and their deeper portions are dilated and tortuous, while the interglandular tissue becomes crowded with epithelial-like cells (*decidual cells*). The mucous membrane, thus altered, is named the *decidua vera*; it lines the cavity of the uterus as far as the os internum, without, however, occluding the orifices of the Fallopian tubes. When the fertilized ovum reaches the uterus, which is thus prepared for its reception, it becomes attached to the decidua, in most cases in the neighborhood of the fundus uteri. The decidua then grows up around the ovum and ultimately covers it in. The part of the decidua which grows up to envelop the ovum is named the *decidua reflexa*; that portion to which the ovum originally became attached is termed the *decidua serotina*, and from it the maternal part of the placenta is derived. After conception the cervix uteri is closed by a plug of mucus (Fig. 708).

By the fourth month the decidua vera has acquired a thickness of about half

¹ Indeed, it would appear, from the researches of His, that in the human embryo the allantois is formed unusually early, being present from a very early period as a stalk of mesoblast connecting the posterior extremity of the embryo with the chorion. This stalk is termed the *abdominal stalk* (Bauchstiel).

an inch, and consists of the following strata: (1) *Stratum compactum*, next the free surface, in which the uterine glands are little altered and where they preserve a comparatively narrow lumen lined by columnar epithelium; between the glands are large numbers of decidual cells. (2) *Stratum spongiosum*, in which the gland tubes are very tortuous and greatly dilated, while their lining cells are flattened or cubical. (3) *Basal layer*, next the uterine muscular wall, in which the glands are not dilated and where they retain their columnar epithelium. It is through this basal layer that the placenta is separated after the birth of the child (Fig. 707).

The decidua reflexa is gradually expanded by the growing ovum, and ultimately comes into contact and blends with the decidua vera so as completely to obliterate the uterine cavity. This obliteration is followed by the degeneration of the decidua; the glands of the decidua reflexa become atrophied, and the entire decidua practically disappears, while the decidua vera is much thinned and its glands also disappear, except their deepest portions, which persist in the basal layer.

In this manner the embryo becomes surrounded by three membranes: (1) the *amnion*, derived, in the case of reptiles, birds, and some mammals, from the outer layer of the mesoblast and the epiblast; (2) the *chorion*, formed by the allantois (which is derived from the hypoblast and inner layer of the mesoblast) and the false amnion; and (3) the *decidua*, derived from the mucous membrane of the uterus.

Much additional interest has been given to the physiology of the decidua by the fact, which seems to be now established by the researches of Sir John Williams, that every discharge of an ovum, whether impregnated or not, is, as a rule, accompanied by the formation of a decidua, and that the essence of menstruation consists in the separation of a decidual layer of the mucous membrane from the uterus; while in the case of pregnancy there is no exfoliation of the membrane, but, on the contrary, it undergoes further development in the manner described above.

Formation of the Placenta.—The placenta is developed partly from maternal and partly from foetal tissues—the maternal portion being derived from the decidua serotina, the foetal from the villi of the chorion frondosum. These villi penetrate the decidua serotina, which then undergoes a series of complicated and, as yet, imperfectly understood changes. Decidual cells accumulate between the uterine glands, while the glands with their epithelial lining undergo degeneration—a degeneration which does not, however, extend as deep as the basal layer, where the glands persist, and retain their epithelial lining throughout the entire period of gestation. Ultimately the superficial portion of the decidual tissue disappears, and the uterine vessels become expanded to form a labyrinth of freely communi-

FIG. 707.—Diagrammatic sections of the uterine mucous membrane: (A) of the non-pregnant uterus; (B) of the pregnant uterus, showing the thickened mucous membrane and the altered condition of the uterine glands.

cating blood-channels or sinuses, which are filled with maternal blood, and in which are suspended the now greatly ramified tufts of the chorionic villi. These uterine sinuses anastomose freely with one another, and form, at the edge of the placenta, a venous channel with an irregular calibre, which runs round the whole circumference of the placenta, and is termed the *marginal sinus*. Some of the chorionic villi are attached by fibrous bands to the basal layer of the decidua and to the imperfect septa between the sinuses, but the majority of them hang free.

Circulation through the Placenta.—The maternal blood is brought to the

FIG. 708.—Sectional plan of the gravid uterus in the third and fourth months. (Modified from Wagner.)

uterine sinuses by the “curling arteries” of the uterus and drained away by the uterine veins, while, as already stated, within the chorionic villi are found the ramifications of the foetal vessels derived from the allantoic or umbilical arteries. Since the villi are suspended in the sinuses, they are necessarily bathed in the maternal blood, and hence it follows that the maternal and foetal blood-currents are brought into close relationship. There is, however, no intermingling of the two currents, or, in other words, no direct communication between the vascular system of the mother and that of the foetus, the interchange of materials necessary for the growth of the foetus and for the purification of the foetal blood taking place through the walls of the villi. The purified blood is carried back to the foetus by the umbilical vein. From what has been said, it will be understood that the placenta is the organ by which the connection between the foetus and the mother is established, and which subserves the purposes of nutrition, respiration, and excretion.

Placenta.—At the end of the gestation period the placenta presents the form of a disk which weighs about a pound and has a diameter of from six to eight inches. Its average thickness is about an inch and a quarter, but diminishes rapidly near the circumference of the disk. Its outer or *decidual* surface blends with the uterine wall, but if examined after the separation of the placenta, it presents a comparatively smooth surface, which on inspection is seen to be incompletely divided into a number of masses named *cotyledons*. Its inner or *chorionic* surface is smooth, being closely invested by the amnion. The umbilical cord is attached near the centre of this surface, and from this attachment the larger branches of the umbilical vessels are seen radiating under the amnion. On section the placenta presents a soft, spongy appearance, caused by its freely communicating blood-

sinuses with their contained villi. Owing to the rapid thinning of the placenta at the periphery of the disk, the decidual and chorionic surfaces come into contact.

Separation of the Placenta.—After the birth of the child the placenta and the membranes (*i. e.*, the amnion and chorion) are expelled as the *after-birth*, the separation of the placenta from the uterine wall taking place through the basal layer of the decidua and necessarily causing rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and this, together with the formation of a blood-clot over the placental site, prevents *post-partum hemorrhage*. The epithelial lining of the uterus is regenerated from the epithelium which lines the persistent portions of the uterine glands in the basal layer of the decidua.

The umbilical cord appears about the end of the fifth week after conception. It consists of the coils of two arteries and a single vein, the *umbilical arteries and vein*, united together by a gelatinous tissue (*jelly of Wharton*). There are originally two umbilical veins, but one of these vessels becomes obliterated, as do also the two omphalo-mesenteric arteries and veins and the duct of the umbilical vesicle, all of which are originally contained in the rudimentary cord. The umbilical cord also contains the remains of the allantois, and is covered externally by a layer of the amnion, reflected over it from the umbilicus.

DEVELOPMENT OF THE EMBRYO.

The further development of the embryo will, perhaps, be better understood if we follow briefly the principal facts relating to the development of the chief parts of which the body consists. *viz.*, the spine, the cranium, the pharyngeal cavity, mouth, etc., the nervous centres, the organs of the senses, the circulatory system, the alimentary canal and its appendages, the organs of respiration, and the genito-urinary organs. The reader is also referred to the chronological table of the development of the fœtus at the end of this section.

Development of the Spine.—The first steps in the formation of the spine have already been traced, *viz.*: (1) The looping up of two longitudinal folds from the cells of the epiblast in front of the primitive streak, to form the *neural groove*, and the gradual growing together of the *laminae dorsales* so as to convert the groove into the *neural canal*. (2) The formation on the ventral aspect of this groove of a continuous cellular cord, the *notochord* or *chorda dorsalis* (Fig. 700), which extends from the cephalic to the caudal extremity of the embryo, and lies in the situation which is afterward occupied by the bodies of the vertebræ. (3) The segmentation of the paraxial mesoblast on either side of the neural canal into a number of quadrilateral masses, the *protovertebræ* or *mesoblastic somites* (Fig. 701). The process of segmentation commences in the cervical region and proceeds successively through the other regions of the spine until a number of segments are formed, which correspond very closely to the number of the permanent vertebræ. Subsequently the protovertebral somites divide into two parts—a ventral and a dorsal. From the ventral division the vertebræ are formed; the dorsal is termed the *muscle-plate*, and from it the muscles of the back are developed. From the ventral division of the protovertebral somites masses of cells are budded off, which grow inward toward the middle line, those from opposite sides meeting and enclosing the notochord and extending dorsally around the neural canal, which they also envelop. Fusion of the ventral divisions also occurs in the antero-posterior direction, so that all trace of their originally segmented condition is lost and the notochord and spinal cord are surrounded by a continuous investment of mesoblast, the *membranous vertebral column*. This investment also extends forward and envelops the primitive brain, forming the *membranous* or *primordial cranium*. From this investment the base of the skull, the vertebræ and their ligaments, and the membranes of the cerebro-spinal nervous system are developed. The future vertebræ make their first appearance about the beginning of the second month in the form of two small masses of cartilage which

are seen in the membranous vertebral column, one on each side of the notochord. These small masses lie opposite to the intervals between the muscle-plates and so alternate with these structures. They are soon joined across the middle line on the ventral aspect of the notochord by a hypochordal cartilaginous bar, which ultimately disappears, except in the case of the atlas vertebra, where it forms the anterior arch of that bone. The vertebral bodies are formed immediately to the dorsal aspect of these hypochordal bars, alternating with the muscle-plates which represent the original mesoblastic somites. The notochord contained in the centre of this chondrifying mass does not continue to grow, but becomes in the human subject relatively smaller, so as, at last, to form a mere slender thread, except opposite the intervals between the bodies of the permanent vertebræ. Here it presents thickenings and

FIG. 709.—Cervical part of the primitive vertebral column and adjacent parts of an embryo of the sixth day, showing the division of the primitive vertebral segments. (From Kölliker, after Remak.) 1, 1. Chorda dorsalis in its sheath, pointed at its upper end. 2 points by three lines to the original intervals of the primitive vertebræ. 3, in a similar manner, indicates the places of new division into permanent bodies of vertebræ. c indicates the body of the first cervical vertebra; in this and the next the primitive division has disappeared, as also in the two lowest represented, viz., d and the one above; in those intermediate the line of division is shown. 4 points in three places to the vertebral arches; and 5, similarly, to three commencing ganglia of the spinal nerves; the dotted segments outside these parts are the muscular plates.

FIG. 710.—Longitudinal section of vertebral column of an eight weeks' human fetus. (Kölliker.)

forms an irregular network, the remains of which are to be found at all periods of life in the central pulp of the intervertebral disks (Figs. 709, 710, and 711).

Development of the Ribs and Sternum.—The ribs are formed from the muscle-plates of the protovertebral somites, from which also the muscles of the back and the true skin of the body-wall are formed. The ribs consist of extensions of this mesoblastic material, which speedily undergo chondrification, and appear as cartilaginous bars, which become separated from the vertebræ at their posterior extremities. At their anterior ends the nine upper costal bars turn upward and fuse together so as to form a cartilaginous strip bounding a central median fissure. The strips on either side then join in the middle line from before backward, and so give rise to a longitudinal piece of cartilage, which represents the manubrium and gladiolus of the sternum. In the process of development the sternal attachment of the eighth rib disappears, while that of the ninth subdivides, one portion remaining attached to the inferior extremity of the cartilaginous sternum and becoming developed into the ensiform cartilage, the other portion receding from the sternum and becoming attached to the cartilage of the eighth rib.

The further development of the vertebræ, ribs, and sternum, and the ossification of their cartilaginous framework, are described in the body of the work.

Development of the Cranium and Face.—It has been seen that the first trace of the embryo consists in the formation of a longitudinal fold of the epiblast on either side of the neural groove, and that these folds or ridges grow backward and meet in the median line, thus forming the neural canal. This canal, at the cephalic extremity of the embryo, is dilated and forms a bulbous enlargement. The bulbous enlargement soon expands into three vesicular dilatations, the three *primary*

cerebral vesicles, from which all the different parts of the encephalon are developed. The primary cerebral vesicles at this time freely communicate with each other at the points of constriction.

The three cavities are lined by epiblast and covered by the same structure. Between these two layers of epiblast a layer of mesoblast spreads over the whole surface of the cerebral vesicles and forms the membranous cranium. From these structures the cranium and its contents are developed. The external layer of the epiblast forms the epidermis and hairs of the scalp. The mesoblastic layer forms the true skin, the blood-vessels (all but their endothelial lining), muscles, connective tissue, bones of the skull, and membranes of the brain. The layer of epiblast lining the vesicles forms the nervous substance of the encephalon, while the vesicles themselves constitute the ventricles.

FIG. 711.—Sagittal section through the intervertebral disk and adjacent parts of two vertebrae of an advanced sheep's embryo. (Kölliker)

The cephalic end of the notochord terminates in a pointed extremity which extends as far forward as the situation of the future basi-sphenoid, and is imbedded in a mass of mesoblast, the "investing mass of Rathke." The posterior part of this mass, which corresponds to the future basi-occipital, shows a subdivision into four segments, the three roots of the hypoglossal nerve indicating their lines of separation. Two cartilaginous bars, the *parachordal cartilages*, then become developed in this investing mass, and these surround the notochord, meeting first on its ventral and next on its dorsal aspect to form the *basilar plate*, the anterior margin of which forms the future *dorsum sellæ*. From this plate are developed the basi-occipital and basi-sphenoid, and by lateral expansions from it the ex-occipitals and the greater wings of the sphenoid. On either side of the parachordal cartilage a cartilaginous capsule, the *labyrinthine* or *periotic cartilage*, surrounds the otic vesicle, and from it the petrous and mastoid portions of the temporal bone are developed. In front of the investing mass of Rathke two lateral bars are directed forward, enclosing between them a space, which forms the pituitary fossa, in which the pituitary body is eventually developed. These bars are named the *prechordal cartilages* or *trabeculae cranii*, and extend as far forward as the anterior extremity of the head, where they coalesce with each other to form the *ethmoid plate* (Fig. 712). This encloses the olfactory pits forming the cartilaginous nasal capsule, from which the ethmoid and turbinated bones are developed. A portion of the ethmoid plate remains unossified and constitutes the cartilaginous part of the nasal septum and the cartilages of the outer nose. From the *trabeculae cranii* the pre-sphenoid is developed, and from this two lateral expansions extend to form its

lesser wings; each of these arises by two roots, one above and one below the optic nerve, and, uniting outside the nerve, enclose the optic foramen. The base of the primitive cranium therefore consists of two parts, *prechordal* and *parachordal*: the former receives the organ of smell and is indented by the eyeball; the latter surrounds the auditory vesicle. Thus it will be seen that the bones which form the

FIG. 712.--Diagrams of the cartilaginous cranium. (Wiedersheim.)

base of the skull are preceded by masses of cartilage, which together form the *chondrocranium*. Those of the vault of the skull, on the other hand, are of membranous formation, and are termed *dermal* or *covering bones*. They are developed in the mesoblast which lies superficial to the primordial cranium, or in that which lies subjacent to the epithelial lining of the foregut. They comprise the upper portion of the tabular part of the occipital (interparietal), the squamous-temporals and tympanic rings, the two parietals, the frontal, the vomer, the internal pterygoid plates, and the bones of the face. Some of them remain distinct throughout life (*e. g.*, parietal and frontal), while others join with the bones of the chondrocranium (*e. g.*, interparietal, squamous-temporal, and internal pterygoid plates).

The head at first consists simply of a cranial cavity, the face and neck being subsequently developed in the manner now to be described.

In all vertebrate animals there is at one period of their development a series of grooves in the upper neck region of the embryo. These are named the *branchial* or *visceral clefts*, and in man are four in number from before backward. They take origin as paired grooves or pouches from the side of the pharynx, and over each groove a corresponding indentation of the epiblast occurs, so that the latter comes into contact with the hypoblast lining the pharynx, and these two layers unite to form thin septa, along the bottom of the grooves, between the pharyngeal cavity and the exterior. In gill-bearing animals these septa disappear and the grooves become complete clefts, the gill clefts, opening from the pharynx on to the exterior; perforation does not, however, occur in birds and mammals. In front and behind each cleft the mesoblast becomes thickened in the form of arches, the *branchial arches* (Figs. 713, 750). In the human embryo there are five pairs of these arches, one in front of the first cleft, one behind the last, and the three remaining ones between the first and second, the second and third, and the third and fourth clefts, respectively. The first arch is named the *mandibular*; the second the *hyoid*; the third the *thyro-hyoid*, while the fourth and fifth have no distinctive names. In each arch there is developed a cartilaginous bar which gives

it firmness and stability, and in each there is also found one of the primitive aortic arches. Continuous with the dorsal end of the first arch and growing forward from it is a triangular process, the *maxillary process* (Figs. 714, 716, 738). Ventrally it is separated from the mandibular arch by a V-shaped notch; the first branchial arch may therefore be said to divide into two, viz., the mandibular arch

FIG. 713.—Profile view of the head of a human embryo, estimated as twenty-seven days old. (After His.)

and the maxillary process. In front of the mandibular arch is a pentagonal depression, termed the *oral sinus* or *stomodæum*, since it forms the future mouth. It is bounded anteriorly by a median process, the *fronto-nasal* process, and laterally by the maxillary processes (Fig. 714), and will be referred to again.

These parts must now be considered with a little more detail.

The *fronto-nasal process* covers the forebrain and contains the coalesced portion of the trabeculæ cranii; it consists of a central or *mid-frontal* process and two lateral parts. By the invagination of the *olfactory pits*, which communicate below with the cavity of the mouth, each lateral portion is subdivided into an *outer* and an *inner nasal process*—the latter having been termed by His the *processus globularis*. The lateral nasal process is separated from the maxillary process by a groove which extends from the eye to the olfactory pit; this is the rudiment of the lachrymal duct (Figs. 714, 715, and 716). The globular processes are prolonged backward as plates, termed the *nasal laminae*; these laminae are at first some distance apart, but, gradually approaching, they ultimately fuse and form the nasal septum, while the globular processes themselves meet in the middle line and form the præmaxillæ and central part of the upper lip (Fig. 717). The depressed part of

FIG. 714.—Under surface of the head of a human embryo, about twenty-nine days old. (After His.)

the midfrontal process between the globular processes forms the lower part of the nasal septum, while above this is seen a prominent angle which becomes the future point, and still higher, a flat area, the future bridge of the nose (Figs. 717, 718). The alæ of the nose are developed from the lateral nasal processes.

FIG. 715.—Under surface of the head of a human embryo, about thirty days old. (After His.)

esses, and with them complete the alveolar arch and upper lip. Finally a pair of palatal processes are formed by inward extensions of the maxillary processes; these coalesce with each other in the median line, thus separating the cavity of the mouth from the nasal fossæ, and completing the palate (Fig. 717). In front the palatal processes join with the premaxillæ, except in the middle line, where a cleft remains which constitutes the naso-palatine canal.

The mandibular arch, by its junction with the corresponding process on the other side, forms the lower jaw or mandible. The cartilaginous rod which it contains has long been known as the "cartilage of Meckel." The proximal end of this cartilage is in contact with the periotic capsule, and from it are developed two of the ossicles

The maxillary processes descend for a short distance, forming the outer wall of the orbit, in which the malar bone is developed; they then incline inward, and, meeting the lateral nasal process, form the floor of the orbit, and shut it off from the rest of the face; continuing their course downward and inward, they join the globular processes,

FIG. 716.—The head and neck of a human embryo thirty-two days old, seen from the ventral surface. The floor of the mouth and pharynx have been removed. (His.) (From Marshall's *Vertebrate Embryology*.)

of the middle ear. the malleus and incus¹ (Fig. 719). The remainder of the rod is associated with the formation of the lower jaw, though the greater part of that bone is developed from membrane. The second visceral arch is named the *hyoid* arch: from it are formed the styloid process, the stylo-hyoid ligament, and the lesser cornu of the hyoid bone. The third, or *thyro-hyoid* arch, gives origin to the

¹ The incus is by some regarded as arising from the proximal end of the hyoid bar.

great cornu of the hyoid bone, while the body of this bone is formed between the second and third arches. The *fourth* and *fifth* arches are rudimentary.

Between the maxillary processes and the mandibular arch the buccal cavity or mouth is formed. As has already been stated (page 1157) the cephalic end of the

FIG. 717.—The roof of the mouth of a human embryo of about two and a half months old, showing the mode of formation of the palate. (His.) (From Marshall's *Vertebrate Embryology*.)

embryo becomes remarkably curved on itself, the fore-brain and mid-brain bending downward over the anterior portion of the original blastodermic vesicle, which is thus enclosed within the body of the embryo and constitutes the fore-gut; the fore-gut terminates in a blind extremity beneath the head (Figs. 720 and 759). Another prominence, the rudimentary heart, appears on the ventral surface of the fore-gut. Between these two prominences, caused by the projection of the fore-brain and the heart, an involution of the epiblast takes place, gradually deepening until it comes in contact with the blind end of the fore-gut. This is the *oral pit* or *stomodæum*, already referred to; it presents the form of a pentangular opening, bounded in front by the fronto-nasal process, behind by the mandibular arch, and laterally by the maxillary processes. From the beginning the mesoblast is absent in the region of the oral pit, and hence its epiblastic lining meets the hypoblastic covering of the blind anterior end of the fore-gut and forms a thin septum, the *pharyngeal septum* (Fig. 759); this soon breaks down, and a communication is established between the mouth and the future pharynx. The oral pit or stomodæum is not equivalent in extent to the adult mouth, since the latter includes the tongue, which is developed from the floor of the pharynx; in fact, as His has pointed out, the anterior pillars of the fauces are developed from the second branchial or hyoid arch.

From the upper part of the stomodæum a pocket-like involution of the epiblast, the *pouch of Rathke*, extends upward between the trabeculae cranii toward the thalamencephalon. This involution ultimately loses its connection with the stomodæum, and, becoming applied to the infundibulum, forms the anterior lobe of the pituitary body (Fig. 720).

The anterior visceral arches grow more rapidly than the posterior, with the result that the latter become telescoped within the former, and a deep depression, the *sinus præcervicalis*, is produced. This sinus is bounded in front by the hyoid arch, and ultimately becomes obliterated by the fusion of its anterior and posterior walls.

FIG. 718.—Head of a human embryo of about eight weeks, in which the nose and mouth are formed. (His.)

Before leaving the subject of the visceral arches and clefts it is necessary to mention that the clefts disappear early in embryonic life, with the exception of portions of the first, which remain permanent—the inner portion, or the Eustachian tube and tympanum; the outer, as the external auditory meatus, while the septum

FIG. 719.—Head and neck of a human embryo eighteen weeks old, with Meckel's cartilage and hyoid bar exposed. (After Kölliker.)

between the two portions becomes invaded by mesoblast and forms the *membrana tympani*.

Development of the Nervous Centres and the Nerves.—The medullary or neural groove already described (page 1155) is the rudiment of the cerebro-spinal axis. As has been seen, this groove is converted into a canal (the neural canal): its cephalic end becomes dilated into a sac, from which the brain is developed; the remainder forms the spinal cord. The cavity of the canal becomes the central canal of the spinal cord, and that of the upper dilated portion the ventricles of the brain. The wall of the canal, formed of epiblastic cells, undergoes great changes, and from it the nervous matter and neuroglia are developed. It consists at first of a layer of columnar epithelium, covered on its exterior by a basement-membrane. The wall becomes thickened, partly by the elongation of the columnar cells and partly by the formation of new cells. The elongation of the columnar cells, now called *spongioblasts*, is followed by the breaking up of their outer ends into a reticulum, which is termed the *myelo-spongium*, and eventually forms the neuroglia. The new cells which are formed appear between the inner ends of the columnar cells as rounded masses, which speedily divide, and are termed *neuroblasts*; they become pear-shaped, and projecting from each of them is a tapering process which perforates the basement-membrane. These neuroblasts are the primitive nerve-cells, and their tapering processes the rudimentary axis-cylinders of the cells (Figs. 721 and 722).

It will be convenient, in the first place, to trace the changes which take place in the cavity of the cerebro-spinal axis, ignoring for a time those which go on in the enclosing wall. But before doing so, it is necessary to mention that, in consequence of the curve which the cephalic portion of the embryo undergoes, a marked bend forward of the canal takes place, so that the plane of the ventricles is almost at right angles with the long axis of the central canal of the cord.

The early stage thus consists of a hollow sac, which is the rudimentary brain, and a hollow canal, which is the rudimentary cord; the sac and the canal freely communicate with each other. The sac first of all becomes elongated; then two constrictions appear in it, which partially divide it into three; these are named *anterior*, *middle*, and *posterior cerebral vesicles*, or the *fore-brain*, *mid-brain*, and

hind-brain (Fig. 701). Subsequently the anterior and posterior vesicles each become constricted into two, while the middle one remains undivided. It will thus be seen that at the anterior extremity of the medullary canal there are five dilata-tions, separated from each other by constrictions, through which, however, they freely communicate with each other. These five vesicles are the five fundamental divisions of the adult brain, and are named from before backward: prosencephalon, thalamencephalon, mesencephalon, epencephalon, and metencephalon (Figs. 723

and 725). They are at first fairly uniform in size and shape, but soon begin to grow at different rates and assume different forms. The changes are most marked in the first vesicle.

The first secondary vessel (*prosencephalon*) sends out two hollow protrusions, one on either side, from the forepart of its lateral surface; these grow rapidly and spread out and extend forward, laterally, and backward over the sides of the first and second vesicles, forming large cavities, which become the lateral ventricles (Fig. 725, g). From each, three prolongations take place: one, forward and outward; a second, backward and inward; and a third, at first backward, outward, and downward, and then forward and inward; these form the horns of the lateral ventricles. These prolongations far exceed in size the original vesicle from which they sprang, which does not increase to any great extent. It remains as the anterior part of the third ventricle (Fig. 725, A), and

the communication between it and the future lateral ventricle persists as the *foramen of Monro* (Fig. 725, H).

FIG. 721.—Transverse section of the spinal cord of a human embryo at the beginning of the fourth week. (After His.) The top of the figure corresponds to the lining of the central canal.

The second vesicle (*thalamencephalon*) becomes elongated from before backward and compressed laterally so as to form the greater part of the third

ventricle (Fig. 725, B). From each side of that part of the forebrain which ultimately becomes the second vesicle is budded off a hollow projection, the primary optic vesicle, which is developed eventually into optic nerve and retina: it will be considered later on. The constriction between the first and second vesicle disappears, so as to throw the whole of the cavity (the future third

ventricle), formed by the remains of the first vesicle and the whole of the second vesicle, into one.

The third vesicle (*mesencephalon*) is converted into a narrow channel, the *iter a tertio ad quartum ventriculum* (Fig. 725, c).

The fourth vesicle (*epencephalon*) becomes widened out, and assumes a triangular form, with its apex directed forward, and situated at the original point of constriction where the third vesicle joins the fourth. It is at the same time flattened from above downward, and constitutes the anterior half of the fourth ventricle (Fig. 725, d).

The fifth vesicle (*metencephalon*) undergoes the same change in form as the fourth, becoming triangular in shape and flattened from above downward, but with this difference, that the apex of the triangle is directed backward, and is continuous with the portion of the medullary

canal which goes to form the central canal of the spinal cord (Fig. 725, e). The base is directed forward and is continuous with the base of the triangular space formed by the fourth vesicle; the constriction between the two vesicles having disappeared, the two spaces freely communicate, and together form a rhomboidal cavity which is the fourth ventricle.

These vesicles do not remain in the same plane, but certain definite flexures take place, which result in an alteration of the position of the vesicles to one another. The first of these flexures (*cephalic*) is opposite the base of the middle vesicle, which becomes sharply bent on itself over the end of the notochord. This has the effect of causing the mid-brain to become the most prominent part of the encephalon on the convexity of the curve (Fig. 723). A second flexure (*pontal*), with its curve in the opposite direction, takes place in the epencephalon, and is very abrupt. A third but less marked flexure (*nuchal*) takes place in the metencephalon at its junction with the cord. The first of these curves or flexures remains permanent, but the second and third almost entirely disappear in the further development of the brain.

The manner in which the different parts of the encephalon and cord are formed from the walls of this greatly altered medullary canal must now be considered, and it will be convenient first of all to study the development of the spinal cord.

The lateral walls of the medullary canal become thickened and marked off into two laminæ: a dorsal, or *alar lamina*, and a ventral, or *basal lamina*, the portion of the canal in the mid-line both on its dorsal and ventral surfaces remaining thin, and form the *roof* and *floor plates* respectively (Fig. 724). In the thickened lateral portion the neuroblasts begin to collect into groups; one especially being noticeable in the basal lamina at the situation of the future anterior horn. The processes of this group of cells pass out of the cord and form the anterior nerve-roots: outside this group of cells is the reticulated tissue of the myelospongium, which represents the white matter at this stage, and through which these processes pass obliquely before they leave the cord (Fig. 722). The anterior and posterior columns make their appearance soon after, and as the cornua

FIG. 726.—Median section of brain of human fœtus during the third month. (After His.)

of gray matter grow out from the central mass the fissures begin to appear. The anterior fissure is a cleft left between the lateral halves of the cord. The mode of formation of the posterior fissure is uncertain; many believe that it is a portion of the neural canal, which, dividing into two, forms an anterior part, the *permanent* canal, and a posterior portion, which becomes filled with a septum of connective tissue from the pia mater, and forms the posterior fissure of the cord. Others are of opinion that it is developed independently of the central canal, as a cleft formed by the enlargement of the lateral halves of the cord, into which an ingrowth of connective tissue from the pia mater takes place.

At first the fœtal spinal cord occupies the whole length of the spinal canal, but after the fourth month the spinal column begins to grow in length more rapidly than the cord, so that the latter no longer occupies the lower part of the canal.

The ventricles of the encephalon are developed in the manner above described from the five secondary vesicles into which the primary expansion of the anterior extremity of the medullary tube is differentiated.

The first vesicle or prosencephalon sends out two hollow protrusions, which spread rapidly, and in the walls of these nervous matter is developed, which constitutes the cerebral hemispheres (Fig. 723, H), the cavities remaining as the lateral ventricles. As these hemispheres extend they grow forward in front of the anterior extremity of the primitive brain, and lie side by side, separated by the longitudinal fissure; they also grow upward, and again lying side by side are separated by another portion of the same fissure, containing a thin layer of mesoblast, which forms the *falx cerebri*; behind and laterally they overlap the roof and sides of the other cerebral vesicles, so that by the seventh month they project behind them. In the floor of each of these hemispheres there occurs a local thickening, which forms the *corpus striatum*, which is continuous behind with the optic thalamus, presently to be described. The surface of the hemisphere is at first smooth, but about the fifth month a sulcus or groove appears in either hemisphere just external to the corpus striatum; this is the fissure of Sylvius: subsequently other fissures appear on the surface, three of which are of sufficient depth to cause a projection into the lateral ventricle. These are the hippocampal fissure, corresponding to the hippocampus major of the lateral ventricle; the parieto-occipital fissure, corresponding with the bend of the posterior horn of the ventricle; and the calcarine fissure, corresponding with the projection of the *calcar avis*.

The remainder of the first vesicle and the second, as we have seen, form the third ventricle; in its normal walls a thickening takes place, which forms the *optic thalamus*. From the floor of this ventricle a hollow protrusion passes downward, and is intimately connected with a diverticulum from the stomodæum, to form the *pituitary body* or *hypophysis cerebri* (Figs. 720, 723, and 726). The greater part of the roof of the third ventricle is very thin, and with the pia mater forms the *velum interpositum*; from its posterior part an outgrowth of cells forms the *pineal body* or *epiphysis cerebri*. Where the cerebral hemispheres are not separated in the middle line by the *falx*, in front and for some distance backward over the roof of the third ventricle their mesial surfaces come in contact, and to a certain extent fuse together, leaving however a small portion where no union takes place, and thus a slit-like cavity is left; this is termed the *fifth ventricle*, though it will be at once seen that its development is quite different from that of the other ventricles. Its lateral walls form the *septum lucidum*. The roof of this cavity becomes thickened, and nerve-fibres pass across from the one hemisphere to the other to form the *corpus callosum*, while in its floor longitudinal fibres are developed to form the *fornix*.

The third vesicle, the cavity of which forms the *iter a tertio ad quartum ventriculum*, develops in its roof four well-marked thickenings, which together form the *corpora quadrigemina*, while its lateral regions become thickened to form the *crura cerebri* (Fig. 726).

The dorsal surface of the fourth vesicle, or epencephalon, forms the covering of the fourth ventricle, and in it a thickening occurs, which is developed into the *cerebellum*; its ventral and lateral regions form the *pons* (Fig. 726).

In the fifth vesicle or metencephalon the lateral parts increase and grow downward on each side toward the middle line, forming the *medulla*, while the dorsal surface assists in forming the roof of the fourth ventricle.

On making a transverse section of the lower part of the fourth ventricle, the alar and basal laminae, already referred to as being present in the cord, are readily recognized, while the thin roof-plate is seen to be greatly expanded laterally. The dorsal part of the alar lamina becomes folded outward and downward, forming what is termed the *rhomboid lip* (Fig. 727). This is at first separated by a groove from the lateral aspect of the alar lamina, but ultimately fuses with it. As the central canal of the cord opens out to form the fourth ventricle, the alar and basal laminae come to occupy the floor of the ventricle—the basal lamina lying nearest the mesial plane.

The Nerves.—The nerves are developed, like the rest of the nervous system,

from epiblast. The spinal nerves are developed as follows: close to the point of involution of the epiblast in the median line, that is to say, in the angle of junction of the neural and general epiblast, a cellular swelling, the *neural crest*,

FIG. 727.—Transverse section of medulla oblongata of human embryo. (After His.)

appears and forms a continuous ridge of epiblast on the dorsal aspect of the neural canal (Fig. 728). On this crest enlargements occur corresponding with the middle of each protovertebral segment. These enlargements grow downward between

FIG. 728.—Transverse section of a portion of a chick embryo of twenty-nine hours' incubation. (From Duval's *Atlas d'Embryologie*.)

the neural canal and the protovertebræ, and occupy a position on the lateral wall of the canal. They are the rudiments of the ganglia of the posterior roots, and at first are attached to the neural crest from which they spring, but subsequently this attachment becomes lost, and they then form isolated masses on either side of the neural canal. They consist of oval cells, from either end of which a process eventually springs; one, growing centrally, passes into the embryonic cord and constitutes the posterior root of the nerve; the other, growing peripherally, joins the fibres of the anterior root to form the spinal nerve.

The anterior root is, according to the researches of His, a direct outgrowth of the neuroblasts which are found in the rudimentary cord (Fig. 722). These cells, at first rounded or oval, become pear-shaped, with their tapering prolongations directed outward toward the surface of the cord. These prolongations are the future axis-cylinders of the anterior nerve-roots; they pass out of the cord in bundles and penetrate the mesoblast to join with the fibres of the posterior root, and from the point of union the nerve grows toward its peripheral termination.

Cranial Nerves.—With the exception of the olfactory and optic nerves, which will be specially referred to, the cranial nerves may be developmentally considered

as consisting of two sets: (1) those which arise as outgrowths from neuroblasts situated in the brain, similar to the mode of origin of the anterior spinal nerve-roots; (2) those which arise from ganglionic rudiments situated outside the brain and derived from the neural crest; from the neuroblasts of these ganglionic rudiments one process grows into the brain and the other outward toward the periphery, similar to the arrangement which exists regarding the posterior spinal nerve-roots. To the first group belong the third, fourth, sixth, seventh, eleventh, and twelfth nerves, together with the motor roots of the fifth, ninth, and tenth. To the second group belong the eighth and the sensory roots of the fifth, ninth, and tenth. While, however, the anterior spinal nerve-roots arise in one series from the ventral part of the cord, the cranial motor fibres arise by two sets of roots, *ventral* and *lateral*; the former include the roots of the sixth and twelfth and probably those of the third and fourth, the latter embrace the spinal accessory and the motor roots of the fifth, seventh, ninth, and tenth.

The olfactory lobe, or rhinencephalon, arises toward the end of the fourth week as a protrusion of the antero-ventral part of each cerebral hemisphere (Fig. 726), and extends forward toward the thickened epiblast of the olfactory area (see page 1169). It is subsequently divided by a transverse constriction into two parts: an anterior, which gives rise to the olfactory bulb and tract together with the trigonum olfactorium, and a posterior, which becomes the peduncle of the corpus callosum and the greater part of the anterior perforated space. Neuroblastic cells, formed within the olfactory area, pass out and form a ganglion between the area and the olfactory bulb. From this ganglion cell-processes grow centripetally to form the nerve-roots, and centrifugally to form the olfactory nerves which ramify in the olfactory mucous membrane, while the ganglion itself fuses with the olfactory bulb.

The optic nerve arises as a hollow outgrowth of the brain, which subsequently becomes solid. It will be considered in connection with the development of the eye.

The sympathetic nerves are developed as outgrowths from the ganglia on the roots of the spinal and cranial nerves.

FIG. 729.—Transverse section of head of chick embryo of forty-eight hours' incubation; $\times 55$. (From Duval's *Atlas d'Embryologie*.)

Development of the Eye.—The optic nerve and retina are developed as an outgrowth from the rudimentary brain, which extends toward the side of the head, and is there met by an ingrowth from the epiblast, out of which the lens and the epithelium of the conjunctiva and cornea are developed.

The first appearance of the eye consists in a hollow protrusion of the fore-brain; this is called the *primitive optic vesicle*. It is at first an open cavity communicating by a hollow stalk with that of the cerebral vesicle. As it is prolonged forward, the epiblast lying immediately over it becomes thickened, and then forms a depression which gradually encroaches on the most prominent part of the primitive ocular vesicle; this in its turn appears to recede before it, so as to become at first depressed and then inverted in the manner indicated

in Figs. 729 and 730, so that the cavity of the vesicle is almost obliterated by the folding back of its anterior half, and the original vesicle converted into a cup, the *optic cup*, in which the involuted epiblastic layer, the rudiment of the lens, is received (Fig. 730); at the same time the proximal part of the vesicle becomes elongated and narrowed into a hollow stalk, the *optic stalk*. This cup-shaped cavity consists therefore of two layers: one, the outer, originally the posterior half of the primitive ocular vesicle, is thin, and eventually forms the pigmented layer of the retina;¹ the other layer, the inner, originally the anterior or more prominent half, which has become folded back, is much thicker, and is converted into the nervous layers of the retina (Figs. 730 and 732). Between the two is the remnant of the cavity of the original primary optic vesicle, which finally becomes obliterated by the union of its two layers. When the retina is established, the optic nerve-fibres originate from its cells and grow backward toward the brain, along the optic stalk, and thus convert it into a solid optic nerve. The nerve-fibres become ultimately connected with the mesencephalon, a relationship

which is permanently maintained. The mouth of the optic cup overlaps the equator of the lens as far as the future aperture of the pupil. In this region the inner or retinal layer of the cup does not become differentiated into nervous elements, but remains as a single layer of columnar cells, which becomes applied to the cells of the pigmented layer, and the conjoined strata form the *pars ciliaris pars iridica retinae* of the adult (Fig. 734). As development proceeds the optic cup increases in size, and thus a space is formed between it and the rudimentary lens; this is the *secondary optic vesicle*, and in it the vitreous humor is developed (Figs. 731, c, and 732). The folding in of the primary optic vesicle to produce

¹ This layer was formerly described as belonging to the choroid, but developmentally it is seen to be a part of the retina.

the optic cup not only takes place in front, at its most prominent part, opposite the lens, but also along its postero-inferior aspect, where a cleft or fissure is formed, the *choroidal fissure*, through which the mesoblast extends to form the vitreous humor. This gap or cleft is continued for some distance into the stalk of the optic vesicle, and thus allows a process of the mesoblast to extend down the stalk to form the *arteria centralis retinæ* and its accompanying vein (Fig. 733). After a time the gap or fissure becomes closed, by a coalescence of its margins, but the line of union remains apparent for a considerable period.

The lens is at first a thickening of the epiblast, then a depression or involution takes place, thus forming an open follicle, the margins of which gradually

FIG. 733.—Optic cup and choroidal fissure seen from below, from a human embryo of about four weeks. (Kollmann.)

approach each other and coalesce, forming a cavity, the *lens vesicle*, enclosed by epiblastic cells (Fig. 731, B C). At the point of involution the external layer of epiblast separates from the lens and passes freely over the surface, so that the lens becomes disconnected from the general epiblast, and recedes into the ocular cup, while the cuticular layer covering it is developed into the corneal epithelium. The cells forming the posterior or inner wall of the lens vesicle rapidly increase in size, becoming elongated and developed into the lens-fibres, and, filling up the cavity, convert it into a solid body. The cells on the anterior wall retain their cellular character, and form the anterior lens epithelium of the adult. The secondary optic vesicle, or space between the lens and the hollow of the optic cup (Figs. 731, 7, and 734), contains a quantity of mesoblastic tissue continuous with the general mesoblast through the choroidal fissure. This tissue becomes converted into the vitreous humor, and surrounds the lens with a vascular membrane, the *vascular capsule of the lens*. From the central artery of the retina several branches are prolonged forward through the vitreous body to the capsule of the lens, but by the sixth month these have all undergone atrophy except one, which persists till the ninth month as the *arteria hyaloidea*. It disappears, however, before birth, and its position is indicated in the adult by the *canalis hyaloideus of Stilling*. The front part of the vascular capsule of the crystalline lens forms the *membrana pupillaris*, and also attaches the iris to the capsule of the lens. It disappears about the seventh month. The sclera, cornea, and choroid are developed from the mesoblast surrounding the optic vesicle.

The eyelids are formed at the end of the third month, as small cutaneous folds (Fig. 734), which come together and unite in front of the globe and cornea. This union is broken up and the eyelids separate before the end of foetal life.

The lachrymal sac and nasal duct appear to result from a thickening of the

epiblast in the groove between the lateral nasal and maxillary processes. This thickening becomes hollowed out into a channel, and the lips of the groove meet

FIG. 734.—Horizontal section through the eye of an eighteen days' embryo rabbit; $\times 30$. (Kölliker.)

over it, enclose it, and convert it into a duct, which eventually opens into the nasal fossa.

Development of the Ear.—The first rudiment of the ear appears shortly after that of the eye, in the form of a thickening of the epiblast, on the outside of that part of the third primary cerebral vesicle which eventually forms the medulla oblongata. The thickening is then followed by an involution of the epiblast (Fig. 735), which becomes deeper and deeper, and sinking toward the base of the skull, forms a flask-shaped cavity; by the narrowing of the external aperture the neck of the flask constitutes the *recessus labyrinthi*. The mouth of the flask then becomes closed, and thus a shut sac is formed, the *primitive auditory* or *otic vesicle* (Fig. 736), which by its sinking inward comes to be placed between the ali-sphenoid and basi-occipital matrices. From it the epithelial lining of the labyrinth is formed. The primary otic vesicle becomes imbedded in a mass of mesoblastic tissue, which rapidly undergoes chondrification and ossification. The vesicle is at first flask- or pear-shaped; the neck of the flask, or *recessus labyrinthi*, prolonged backward, forms the aquæductus vestibuli. From it are given off certain prolongations or diverticula, from which the various parts of the labyrinth are formed. One from the anterior end gradually elongates, and, forming a tube, bends on itself and becomes the cochlea. Three others, which appear on the surface of the vesicle, form the semicircular canals, of which the external canal is the last to be developed (Figs. 738 and 739). Subsequently a constriction takes place in the original vesicle, which nearly divides it into two, and from these are formed the utricle and saccule (Fig. 739). Finally, the auditory nerve, which has been devel-

FIG. 735.—Section through the head of a human embryo, about twelve days old, in the region of the hind-brain. (Kollmann.)

oped from the "neural crest" in the manner above described (page 1180), pierces the auditory capsule in two main divisions—one for the vestibule, the other for the cochlea. The middle ear and Eustachian tube are the remains of the inner part of the first branchial cleft (hyomandibular), and are closed externally by the *membrana tympani*, which originally consists of a layer of epiblast externally, and a layer of hypoblast internally; between these two layers the mesoblast extends to form the *substantia propria* of the membrane. With regard to the exact mode

FIG. 736.—Section through hind-brain and otic vesicle of an embryo more advanced than that of Fig. 735. (After His.)

FIG. 737.—Left auditory vesicle of a human embryo of four weeks, seen from the outer surface. (W. His, Jr.)

of development of the ossicles of the middle ear there is considerable difference of opinion. The most probable view is that the *incus* and *malleus* are developed from the proximal end of the mandibular (Meckel's) cartilage (Fig. 719): that the base of the *stapes* is formed by the ossification of the cartilage which fills in the foramen ovale and its arch from the ossified proximal end of the hyoidean arch.

The external auditory meatus is formed from the outer part of the hyo-

FIG. 738.—Left auditory vesicle of a human embryo of five weeks, seen from the outer surface. (W. His, Jr.)

mandibular cleft, while the pinna is developed by the gradual differentiation of a series of processes which appear around the outer margin of the cleft (Fig. 741).

Development of the Nose.—The olfactory fossæ, like the primary auditory vesicles, are formed in the first instance by a thickening and involution of the epiblast, which takes place about the fourth week, at a point below and in front of the ocular vesicle (Fig. 723). The borders of the involuted portion very soon become prominent, in consequence of the development of the mesial and lateral nasal processes already referred to (page 1169), and which are formed on either side of the rudimentary fossa (Figs. 714, 715). As these processes increase, the fossa deepens

and becomes converted into a channel, which eventually forms the olfactory region of the nose; this comprises the portion to which the olfactory nerves are distributed. At this time the nasal cavity is continuous with the buccal cavity; but as the palatal septum is formed, the buccal cavity is divided into two parts, the upper of which

FIG. 739.—Transverse section through head of foetal sheep, in the region of the labyrinth. $\times 30$. (After Boettcher.)

forms the lower part of the nasal fossæ, while the remainder forms the permanent mouth. On the mesial wall of the nasal fossa a small blind pit of epiblast becomes invaginated and extends backward into the nasal septum. This forms the rudiment of *Jacobson's organ*, which ultimately becomes partly enclosed in a curved cartilaginous plate derived from a cartilage of the nasal septum.

FIG. 740.—Transverse section of the canal of the cochlea of a foetal cat. (After Boettcher and Ayres.) (From Kollmann's *Entwicklungsgeschichte*.)

The development of the external nose has already been described. It is perceptible about the end of the second month. The nostrils are at first closed by epithelium, but this disappears about the fifth month.

The olfactory lobe (rhinencephalon) is formed, as already explained, by an evagination of the anterior cerebral vesicle.

Development of the Skin, Glands, and Soft Parts.—The epidermis and its appendages, consisting of the hairs, nails, sebaceous and sweat glands, are developed from the epiblast, while the corium or true skin is of mesoblastic origin. About the fifth week the epidermis consists of two layers of cells, the deeper one corresponding to the rete mucosum. The subcutaneous fat forms about the fourth month, and the papillæ of the true skin about the sixth. A considerable desquamation of epidermis takes place during fetal life, and this desquamated epidermis, mixed with a sebaceous secretion, constitutes the *vernix caseosa*, with which the

FIG. 741.—Left ears of human embryos, estimated at thirty-five and thirty-eight days respectively. (After His.)

skin is smeared during the last three months of fetal life. The nails are formed at the third month, and begin to project from the epidermis about the sixth. The hairs appear between the third and fourth months in the form of solid downgrowths of the deeper layer of the epidermis, which then become inverted by papillary projections from the corium. About the fifth month, the fetal hairs (*lanugo*) appear, first on the head and then on the other parts; they drop off after birth, and give place to the permanent hairs. The cellular structure of the sudoriferous and sebaceous glands is formed from the epiblast, while the connective tissue and

FIG. 742.—Head of chick embryo of about thirty-eight hours' incubation, viewed from the ventral surface. (From Duval's *Atlas d'Embryologie*.)

blood-vessels are derived from the mesoblast. The mammary gland is also formed partly from mesoblast and partly from epiblast—its blood-vessels and connective tissue being derived from the former, its cellular elements from the latter. Its first rudiment is seen about the third month, in the form of a small projection inward of epithelial elements, which invade the mesoblast; from this, similar tracts of cellular elements radiate; these subsequently give rise to the glandular

follicles and ducts. The development of the former, however, remains imperfect, except in the adult female.

Development of the Limbs.—The upper and lower limbs begin to project, as buds, from the anterior and posterior part of the embryo about the fourth week. These buds are formed by a projection of the somatopleure from the point where the mesoblast splits into its parietal and visceral layers, just external to the vertebral somites, of which they may be regarded as lateral extensions. The division of the terminal portion of the bud into fingers and toes is early indicated, and soon a notch or constriction marks the future separation of the hand or foot from the forearm or leg. Next, a similar groove appears at the site of the elbow or knee. The indifferent tissue, of which the whole projection is at first composed, is differentiated into muscle and cartilage, before the appearance of any internal clefts for the joints between the chief bones.

The muscles become visible about the seventh or eighth week. The voluntary muscles are developed from the muscle-plates of the protovertebral somites, which are at first segmentally arranged on either side of the rudimentary spine. Each muscle-plate becomes differentiated into two parts, superficial and deep. The former is termed the *cutis plate*, and from it the corium or true skin is developed, while the latter becomes developed into longitudinal groups of muscle-fibres, extending forward into the neck and head region of the embryo and laterally to enclose the cavities of the thorax and abdomen. The muscles of the limbs are also

FIG. 743.—Heart of human embryo of about fifteen days. (Reconstruction by His.)

formed from the same source, being produced by outgrowths from the protovertebral somites in those situations where the limb buds appear. The involuntary muscles are derived from the splanchnopleure mesoblast, and are therefore not connected in any way with the protovertebral somites.

Development of the Blood-vascular System.—There are three distinct stages in the development of the circulatory system, each in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the *vitelline circulation*, during which nutriment is extracted from the *vitellus* or contents of the yolk-sac. In the second stage there is the *placental circulation*, during which nutrition is obtained by means of the placenta from the blood of the mother. In the third stage there is the *complete circulation of the adult*, commencing at birth, during which nutrition is provided for by the organs of the individual itself.

1. The **vitelline circulation** is carried on partly within the body of the embryo, and partly external to it in the vascular area of the yolk-sac. It consists of a median tubular heart, from which two vessels (arteries) project anteriorly. These carry the blood to a plexus of capillaries spread over the vascular area, from which

the blood is returned by two vessels (veins) which enter the heart posteriorly, and thus a complete circulation is formed (Fig. 744).

In these vessels and the heart a fluid (*blood*) is contained, in which rudimentary corpuscles are found. The mode of formation of these elementary parts must first be considered.

In mammalia the heart is formed by a longitudinal fold of the splanchnopleure with its underlying hypoblast on either side of the median line in front of the anterior extremity of the rudimentary pharynx, at about the level of the posterior primary cerebral vesicle. The folds become tubes, their walls thicken and present two distinct strata of cells: the inner and thinner layer, derived from the hypoblast, forms the endocardium; the outer and thicker, derived from the visceral mesoblast, forms the muscular wall of the heart. In its primitive condition, the heart consists therefore of a pair of tubes, one on either side of the body. These, however, soon coalesce in the median line, and, fusing together, form a single central tube.¹ Each of the two primary tubes receives posteriorly a large vein (the omphalo-mesenteric vein), and is prolonged anteriorly into an artery (the primitive aorta). So that after fusion of the heart-tubes has taken place there is, in the primitive vitelline circulation, as above mentioned, a single tubular heart,

FIG. 744.—Human embryo of about fourteen days, with yolk-sac. (After His.) (From Kollmann's *Entwicklungsgeschichte*.)

with two arteries proceeding from it and two veins emptying themselves into it. The first blood-vessels are developed as follows: The nucleated embryonic cells of the mesoblast send out processes in various directions. These processes fuse together, and an irregular network is formed. The nuclei of the cells multiply, and, accumulating around themselves a small quantity of the protoplasm of the cell, they acquire a tinge of color and form the first red blood-corpuscles. The protoplasm of the cells and their branched network become hollowed out into a system of canals containing fluid, in which the newly formed corpuscles float (Fig. 745).²

The earliest blood-corpuscles are all nucleated, and in this and other respects—that is, in their possession of amœboid movements and in their capability of under-

¹ In most fishes and in amphibia the heart originates as a single median tube.

² Recent observers incline to the view that the blood-corpuscles are of hypoblastic origin, being developed from the endothelium of the vessels, the sequence of the development of the different structures being: first the heart, then the blood-vessels, and lastly the blood-corpuscles. (Consult Dr. Ernest Mehnert's *Biomechanik*, Jena, 1898.)

going multiplication by division—resemble the white corpuscles. Soon, however, true white corpuscles make their appearance, and it seems that they are derived from the rudiments of the thymus gland.¹ The nucleated condition of the red globules ceases before birth. The vitelline circulation commences about the fifteenth day and lasts till the fifth week. When fully established, it is carried on as follows: Proceeding from the anterior end of the tubular heart are two arteries, the primitive aortæ; these run down in front of the primitive vertebræ and behind the walls of the intestinal cavity into the two *omphalo-mesenteric* arteries, which ramify in the *vascular area* of the yolk-sac. Here they terminate peripherally in a circular vessel—the *terminal sinus*, which surrounds the vascular area. The blood is collected from the capillaries of the vascular area into the two *omphalo-mesenteric* veins, which open into the posterior extremity of the heart.

2. The Placental Circulation.—As the umbilical vesicle diminishes, the allantois and the placenta are developed in the manner above described (page 1162). When the umbilical vesicle atrophies the placenta becomes the only source of nutrition for the embryo. The allantois carries with it two arteries (*umbilical* or *allantoic*), derived from the primitive aortæ, and two veins; these vessels become much enlarged as the placental circulation is established, but subsequently one of the veins disappears, and in the later stages of uterine life the circulation is carried on between the fœtus and the placenta by two umbilical arteries and one umbilical vein.

During the occurrence of these changes great alterations take place in the primitive heart and blood-vessels, and now require description.

Further Development of the Heart.—The following is an outline of the changes which take place during the further development of the heart.

The simple tubular heart, already described, becomes elongated and bent on itself, so as to form an S-shaped loop, the anterior part bending to the right and the posterior part to the left. The intermediate portion arches transversely from right to left, and then turns sharply forward into the anterior part of the loop. Slight constrictions make their appearance in the tube and divide it into four parts, viz.: (1) the *sinus venosus* (*sinus reuniens* of His); (2) the common auricle; (3) the common ventricle; (4) the aortic bulb. The common auricle and ventricle communicate by a short canal, the *auricular canal* (Figs. 742, 743, and 746).

The sinus venosus is situated in the septum transversum (a layer of mesoblast from which the ventral part of the Diaphragm is developed) behind the common

¹ Consult an article by J. Beard, *Anatomischer Anzeiger*, December, 1900.

auricle, and is formed by the union of three pairs of veins, viz., (1) the veins or ducts of Cuvier from the body of the embryo; (2) the omphalo-mesenteric veins from the yolk-sac; (3) the umbilical veins from the placenta (Fig. 747). The sinus is at first placed transversely, and opens by a median aperture into the common auricle. Soon, however, it assumes an oblique position, and its right half or horn becomes larger than the left, while the opening into the auricle is found to be in the right portion of the auricular cavity. The right horn ultimately becomes incorporated with and forms a part of the right auricle, the line of union between it and the auricle proper being indicated in the interior of the adult auricle by a vertical crest, the *crista terminalis* of His. The left horn, which ultimately receives only the left duct of Cuvier, persists as the coronary sinus (Fig. 753). The omphalo-mesenteric and umbilical veins are soon replaced by a single vessel, the inferior vena cava, and the three veins (inferior vena cava and right and left Cuvierian ducts) open into the dorsal aspect of the auricle by a common slit-like aperture. The upper part of this aperture represents the opening

FIG. 747.—Heart of a human embryo 4.2 mm. in length, seen from behind. (His.)

of the permanent superior vena cava, the lower part that of the inferior vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is bordered on its mesial and lateral aspects by a fold of endocardium. The mesial part of the fold disappears, while from the lateral part the Eustachian and Thebesian valves are developed. At the lower extremity of the slit is a triangular thickening, the *spina vestibuli* of His, which partly closes the aperture between the two auricles, and which, according to His, takes a part in the formation of both the interauricular and interventricular septum.

The common auricle becomes gradually subdivided into right and left auricles by a septum, the *septum superius*, which grows from its dorsal and upper wall so that the two auricles communicate with each other only below the margin of this septum. This communication (*ostium primum* of Born) does not, however, represent the future foramen ovale, for the septum grows downward and blends with the partition which comes to subdivide the auricular canal. The foramen ovale (*ostium secundum* of Born) results from a perforation of the upper part of the *septum superius*.

The auricular canal is at first a short straight tube connecting the auricular with the ventricular portion of the heart, but it becomes overlapped by the growing auricles and ventricles so that its position on the surface of the heart is indicated only by an annular constriction (Fig. 746). Its lumen is reduced to a transverse slit, and a thickening appears on its dorsal and ventral walls. These thickenings, or *endocardial cushions* as they are termed, project into the canal, and, meeting in the middle line, divide the canal into two channels, the future right and left auriculo-ventricular orifices.

The common ventricle becomes divided by a septum, the *septum inferius*, which

grows upward from the lower part of the ventricle, its position being indicated on the surface of the heart by a furrow. It extends upward almost as far as the auricular canal, but for some time an interventricular foramen exists between it and the septum of the auricular canal (Fig. 748).

FIG. 748.—Showing the development of the septum of the aortic bulb and of the ventricles. (Born.)

The aortic bulb is divided by the *aortic septum*. This makes its appearance at the distal end of the bulb as two ridge-like thickenings of its endothelial lining; these increase in size, and, projecting into the lumen, ultimately fuse to form the septum, and thus the aortic bulb is divided into the pulmonary artery and the aorta. The aortic septum takes a spiral course toward the proximal end of the bulb, so that the two vessels lie side by side above; but near the heart the pulmonary artery is in front of the aorta (Fig. 749). The septum grows down into the ventricle as an oblique partition, which ultimately blends with the septum

FIG. 749.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right, of the figure. (After His.)

inferius of the ventricles in such a way as to bring the left ventricle into communication with the aorta and the right with the pulmonary artery.

Peculiarities of the Foetal Heart.—In early foetal life the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax but lies at first in the middle line; toward the end of pregnancy it gradually becomes oblique. Its auricular portion is at first larger than the ventricular part, and the two auricles communicate freely through the foramen ovale. In consequence of the communication, through the ductus arteriosus, between the pulmonary artery and the aorta, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is as thick as that of the left. At the end of foetal life, however, the left ventricle is thicker than the right, a difference which becomes more and more emphasized after birth.

Further Development of the Arteries.—In the vitelline circulation, two arteries were described as coming off from the primitive heart, and running down in front of the developing vertebræ. The first change consists in the fusion of these arteries into one vessel at some distance from the heart; this vessel is the descending thoracic and abdominal aorta. In consequence of the lengthening of the neck the heart falls backward to its lower part and then into the thorax, and the two original arteries, proceeding from the heart to their point of fusion in the common

descending aorta, become elongated and assume an arched form, curving backward on each side, from the front of the body toward the vertebral column (Fig. 751, A). These are the *first* or *primitive aortic arches*. As the heart recedes into the thorax, and these arches, which correspond in position to the mandibular arch, become elongated, four additional pairs of arches are formed behind them around the pharynx, one in each branchial arch (Fig. 750). The arches, five in number, remain permanent in fishes, giving off from their convex borders the branchial arteries to supply the gills. In many animals the five pairs do not exist together, for the first two have disappeared before the others are formed; but this is not so in man, where all five arches are present and pervious during a certain period of embryonic existence (Fig. 750). Only some of the arches in mammalia remain as

FIG. 750.—Profile view of a human embryo, estimated at twenty or twenty-one days old. (After His.)

permanent structures; the others, or portions of them, become obliterated or disappear. The first two arches entirely disappear. The third remains as a part of the internal carotid artery, the remainder being formed by the upper part of the posterior aortic root—*i. e.*, the descending part of the original vessel which proceeded from the rudimentary tubular heart. The common and external carotid arteries are formed from the anterior aortic root—that is, the ascending portion of the same primitive vessel. The fourth arch on the left side becomes developed into the permanent arch of the aorta in mammals; but in birds it is the fourth arch on the right side which forms the aortic arch; in reptiles the fourth arch on both sides persists, so that these animals possess a permanent double aortic arch. The fourth arch on the right side forms the subclavian artery, and by the junction of its com-

mencement with the anterior aortic root, from which the common carotid is developed, it forms the innominate artery.¹ The fifth arch on the left side forms the pulmonary artery and the ductus arteriosus; that on the right side becomes atrophied and disappears. The first part of the fifth left arch remains connected with that part of the aortic bulb which is separated as the pulmonary stem, and with it forms the common pulmonary artery. From about the middle of this arch two branches are given off, which form the right and left pulmonary arteries,

FIG. 751.—Showing the formation of the aortic arches and the large arteries. I. II. III. IV. V. First, second, third, fourth, and fifth aortic arches. A. Common trunk from which the first pair spring; the place where the succeeding pairs are formed is indicated by dotted lines. B. Common trunk, with four arches and a trace of the fifth. C. Common trunk, with the three last pairs, the first two having been obliterated. D. The persistent arteries, those which have disappeared being indicated by dotted lines. 1. Common arterial trunk. 2. respectively, and the remaining portion—that is, the part beyond the origin of the branches—communicates with the left fourth arch, and constitutes the ductus arteriosus. This duct remains pervious during the whole of foetal life, but after birth becomes obliterated (Fig. 752). A series of intersegmental or intervertebral arteries arise from the primitive dorsal aortæ, those in the neck alternating with the cervical segments of the spine. The intersegmental artery which lies between the sixth and seventh segments forms the lower part of the vertebral artery; its upper part is formed by an antero-posterior anastomosis between the higher intersegmental vessels. The subclavian artery is originally a branch of the vertebral, but, owing to the subsequent growth of the upper limb, it comes to exceed in size the parent trunk.

The development of the arteries in the lower part of the body is going on during the same time. It has been seen that originally there were two primitive aortæ coming off from the simple tubular heart. These two vessels course downward, one on either side of the notochord, and supply the omphalo-mesenteric arteries to the yolk-sac. At the hinder end of the embryo the primitive aortæ give off the two umbilical or allantoic arteries which run in the walls of the allantois to the umbilicus, beyond which they are carried in the umbilical cord to the placenta. The two primitive aortæ soon fuse to form a single vessel, the future descending aorta; the fusion begins in the thoracic region, and from there proceeds backward and forward, and the umbilical arteries now appear as if resulting from the bifurcation of the single vessel; the part of the fused vessels, beyond their origin, is indicated, however, by the middle sacral artery. The common and internal iliac arteries represent the proximal end of the umbilical artery; the remainder of the vessel, with the exception of the part which gives off the superior vesical artery, becomes obliterated after birth; and the obliterated portions of the two umbilical arteries, together with the urachus, carry off the peritoneum from the bladder as its superior false ligament. The external iliac and femoral arteries are developed from a minute branch given off from the umbilical artery near its origin, and are at first of comparatively small size.

¹ This is interesting in connection with the position of the recurrent laryngeal nerve, which is thus seen to hook round the same primitive foetal structure, which becomes on the right side the subclavian artery, on the left the arch of the aorta.

Development of the Veins.—The formation of the great veins of the embryo may be best considered under two groups, visceral and parietal.

The *visceral veins* are the two vitelline or omphalo-mesenteric veins bringing the blood from the yolk-sac, and the two umbilical or allantoic veins returning the blood from the placenta; these four veins open close together into the sinus venosus (Fig. 747).

The vitelline veins run upward at first in front, and subsequently on either side of the intestinal canal. They unite on the ventral aspect of the canal before they reach the liver, and then encircle the intestinal tube by forming around it two venous rings, the first on its dorsal, the second on its ventral aspect. The portions of the veins above the upper ring become invaded by the developing

FIG. 752.—Showing the destination of the arterial arches in man and mammals. (Modified from Rathker.) (From Quain's *Anatomy*, 1890, vol. i., pt. 1.) The truncus arteriosus and the five arterial arches springing from it are represented in outline only; the permanent vessels in shade—those belonging to the aortic system in heavy shaded line, to the pulmonary system in light shaded line.

liver and broken up by it into a network of smaller vessels, the central part of the network consisting of a capillary plexus. The branches which convey the blood to this plexus are named the *venæ advehentes*, and become the branches of the portal vein; while the vessels which drain the plexus into the sinus venosus are termed the *venæ revehentes*, and form the future hepatic veins (Figs. 753 and 754).

The lower part of the *portal vein* is formed from the fused vitelline veins which receive the veins from the alimentary canal; its upper part is derived from the venous rings by the persistence of the left half of the lower and the right half of the upper ring, so that the vessel forms a spiral turn round the duodenum (Fig. 754).

The two umbilical veins fuse early to form a single trunk in the allantois, but remain double for some time in the embryo and pass forward to the sinus venosus in the side walls of the body. Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the invasion of the liver, and thus at this stage the whole of the blood from the yolk-sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical vein

shrivels up and almost entirely disappears; the left, on the other hand, becomes much enlarged after the establishment of the placental circulation, and opens into the upper venous ring. Finally a direct branch is established between this ring and the right hepatic vein; this branch is the *ductus venosus* or *vena ascendens*, and, enlarging rapidly, it forms a wide channel through which most of the blood, returned from the placenta, is carried direct to the heart (Fig. 754).

The Parietal Veins.—The first indication of a parietal system consists in the appearance of two short transverse veins (the *ducts of Cuvier*), which open, one on either side, into the auricular portion of the heart. Each of these ducts is formed by an ascending and a descending vein. The ascending veins return the blood from the parietes of the trunk and from the Wolffian bodies, and are called *cardinal veins*. The descending veins return the blood from the head,

FIG. 753.—Human embryo with heart and anterior body wall removed to show the sinus venosus and its tributaries. (From Kollmann's *Entwicklungsgeschichte*.) (After His.)

and are called *primitive jugular veins* (Fig. 750). The blood from the lower limbs is collected by the iliac veins, which empty themselves into the cardinal veins. In the earlier stages of development the right and left iliac veins open into the corresponding right and left cardinal veins (Fig. 756), but later on a transverse branch connects the lower ends of the two cardinal veins, and through this the blood from the left iliac vein is carried into the right cardinal vein. By the development of a similar transverse branch higher up the blood from the left kidney is also carried into the right cardinal vein (Fig. 755, 2). The portion of the left cardinal vein above the origin of the lower transverse branch becomes atrophied as high as the level of the renal vein, above which it persists as the *vena azygos minor*. The right cardinal vein, which now receives the blood from both lower extremities, forms a large venous trunk along the posterior

abdominal wall; it receives the renal veins from the kidneys, and forms, up to this level, the inferior vena cava. Above the level of the renal veins the inferior vena cava first makes its appearance as a small vein lying in the tissue between the two kidneys. Superiorly it opens into the sinus venosus, while below it com-

FIG. 754.—The liver, and the veins in connection with it, of a human embryo, twenty-four or twenty-five days old, as seen from the ventral surface. (After His.) (Copied from Milnes Marshall's *Embryology*.)

municates with the right cardinal vein near the level of the renal veins (Fig. 755, 1, 2). This small vein ultimately becomes enlarged, and carries the blood upward from the right cardinal vein, and so forms the upper part of the inferior vena cava. The portion of the right cardinal vein above the renal veins persists as the vena

azygos major, and receives the right intercostal veins, while the vena azygos minor is brought into communication with it by the development of transverse branches in front of the spinal column (Fig. 755, 2, 3).

In consequence of the atrophy of the Wolffian bodies the cardinal veins diminish in size; the primitive jugular veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented by receiving the vein (*subclavian*) from the upper extremity, and so come to form the chief veins of the Cuvierian ducts; these ducts gradually assume an

almost vertical position in consequence of the descent of the heart into the thorax. The right and left Cuvierian ducts are originally of the same diameter, and are frequently termed the *right and left superior venæ cavæ*. By the development of a transverse branch (the future *left innominate vein*) between the

FIG. 757.—Diagram of a longitudinal section of a mammalian embryo. Very early. (After Quain.)

two ducts the blood is carried from the left duct into the right, which thus becomes much enlarged and forms the permanent *superior vena cava*, and into which the *vena azygos major* opens. The left duct atrophies; its upper part remains pervious as a small vein, which receives the *left superior intercostal vein*; its intermediate portion is represented by the *vestigial fold* of Marshall; its lower part persists as a small vein, the *oblique vein* of Marshall, which runs downward across the back of the left auricle to join the coronary sinus; this

sinus, as has been indicated, represents the persistent left horn of the sinus venosus. The primitive jugular veins become the internal jugular veins of the adult; the lower part of the right primitive jugular vein forms also the right innominate veins (Figs. 755, 1, 2, 3).

The foetal circulation has been described in the section on the Blood-Vascular System.

Development of the Alimentary Canal.—As already indicated (page 1157), the primitive alimentary canal is formed, at an early stage, by the enclosure within the embryo of a portion of the blastodermic vesicle, and is seen to consist of three parts, viz.: (1) the *fore-gut*, within the cephalic flexure and dorsal to the heart; (2) the *mid-gut*, opening freely into the yolk-sac; and (3) the *hind-gut*, within

the caudal flexure. The fore-gut and hind-gut end blindly, there being at first neither mouth nor anus (Figs. 756 and 757). The formation of the mouth or stomodæum, and the subsequent communication between it and the cephalic end of the fore-gut, have already been considered; the manner in which the anus is formed will presently be discussed.

From the fore-gut are developed the pharynx, œsophagus, stomach, and duodenum, and further, as diverticula from the duodenum, the liver and pancreas; from the hind-gut, the greater part of the rectum, and as a tubular outgrowth from it the hollow stalk of the allantois; the mid-gut gives origin to the remainder, or

FIG. 758.—Early form of the alimentary canal. (From Kölliker, after Bischoff.) In A a front view and in B an antero-posterior section are represented. *a*. Four pharyngeal or visceral plates. *b*. The posterior part of the intestine.

longest section, of the alimentary tube—*i. e.*, the portion which reaches from the duodenum to the rectum.

The upper part of the fore-gut becomes dilated to form the pharynx, in relation to which the branchial arches are developed (Figs. 716 and 759); the succeeding part remains tubular, and with the descent of the stomach is elongated to form the œsophagus. Soon a fusiform dilatation, the future stomach, makes its appearance, and beyond this the mid-gut opens freely into the yolk-sac (Figs. 759 and 760).

This opening is at first wide, but, as the body-walls close in around the umbilicus, it is gradually narrowed into a tubular stalk, the *yolk-stalk* or *vitello-intestinal duct*. At this stage, therefore, the alimentary canal forms a nearly straight tube in front of the notochord and primitive aortæ (Fig. 757). From the stomach to the rectum it is attached to the notochord by a band of mesoblast, from which the common mesentery of the gut is subsequently developed. The stomach undergoes a further dilatation, and its two curvatures can be recognized (Figs. 760 and 764), the greater directed toward the vertebral column and the lesser toward the anterior wall of the abdomen, while of its two surfaces one looks to the right and the other to the left. The mid-gut also undergoes great elongation, and forms a V-shaped loop which projects downward and forward; from the bend or angle of the loop the vitello-intestinal duct passes to the umbilicus (Fig. 764). For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but by the end of the third month this is withdrawn. With the lengthening of the tube, the mesoblast, which attaches it to the future vertebral column and which carries the blood-vessels for the supply of the gut, is

thinned and drawn out to form the *primitive* or *common mesentery*. The portion of this mesentery which is attached to the greater curvature of the stomach is named the *mesogastrium*, and the parts which suspend the colon and rectum are respectively termed the *mesocolon* and *mesorectum* (Fig. 764). About the sixth week a lateral diverticulum makes its appearance a short distance beyond the vitello-intestinal duct, and indicates the future cæcum or boundary between the small and the large intestine. This cæcal diverticulum has at first a uniform calibre, but its blind extremity remains rudimentary and forms the vermiform

FIG. 759.—Human embryo, about fifteen days old. Brain and heart represented from right side; alimentary canal and yolk-sac in mesial section. (After His.)

appendix (Figs. 764, 765). Changes also take place in the position and direction of the stomach. It falls over on to its right surface, which henceforth is directed backward, while its original left surface looks forward; further, its greater curvature is drawn downward and to the left, away from the vertebral column, while its lesser curvature is directed upward, and the commencement of the duodenum is pushed over to the right side of the middle line. The mesogastrium, being attached to the greater curvature, must necessarily follow its movements, and hence it becomes greatly elongated and drawn outward from the vertebral column, and, like the stomach, what was originally its right surface is now directed backward and its left forward. In this way a pouch, the *bursa omentalis*, is formed behind the stomach; this pouch is the future lesser sac of the peritoneum, and it increases in size as the alimentary tube undergoes further development; the entrance to the pouch constitutes the future *foramen of Winslow* (Figs. 761, 765, and 768). The remainder of the canal becomes greatly increased in length, so that the tube is coiled on itself, and this increase in length demands a corresponding increase in the width of the intestinal attachment of the mesentery, so that it becomes plaited or folded.

At this stage the small and the large intestine are attached to the vertebral column by a common mesentery, the coils of the small intestine falling to the right of the middle line, while the large intestine lies on the left side.¹

¹ Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesial plane, where it is continued into the jejunum; the arteries to the small intestine (*rami intestini tenuis*) also arise from the right instead of the left side of the superior mesenteric artery.

The gut now becomes rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cæcum is placed immediately below

FIG. 760.—Sketches in profile of two stages in the development of the human alimentary canal. (His.) Fig. A $\times 30$. Fig. B $\times 20$.

the liver; about the sixth month the cæcum descends into the right iliac fossa, and the large intestine now forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front

of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (Fig. 765). Some-

FIG. 761.—Front view of two successive stages in the development of the alimentary canal. (His.)

times the downward progress of the cæcum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

Further changes take place in the bursa omentalis and in the common mesentery, and give rise to the peritoneal relations seen in the adult. The bursa omentalis, which at first reaches only as far as the greater curvature of the

FIG. 762.—Schematic and enlarged cross-section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)

FIG. 763.—Same section as in Fig. 762, at end of third month. (Toldt.)

stomach, grows downward to form the great omentum, and this downward extension lies in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior wall of the bursa omentalis, but ultimately the two blend, and hence the great omentum appears as if attached to the transverse colon (Figs. 768, 769, and 770). The

mesentery of the duodenum, in which the rudiment of the pancreas is enclosed, disappears, and so this part of the gut becomes fixed to the posterior abdominal wall, and the pancreas lies entirely behind the peritoneal membrane. The mesenteries of the ascending and descending parts of the colon disappear in the majority of cases, while that of the small intestine assumes the oblique attachment characteristic of its adult condition.

FIG. 764.—Abdominal part of alimentary canal and its attachment to the primitive or common mesentery. Human embryo of six weeks. (After Toldt.) (From Kollmann's *Entwicklungsgeschichte*.)

FIG. 765.—Illustrating two stages in the development of the human alimentary canal and its mesentery. The arrow indicates the entrance to the bursa omentalis.

The small omentum is formed by a thinning of the mesoblast or *anterior primitive mesentery*, which attaches the lesser curvature of the stomach to the anterior abdominal wall. By the subsequent growth of the liver this leaf of mesoblast is divided into two parts, viz., the small omentum between the stomach and liver, and the falciform ligament between the liver and the abdominal wall and Diaphragm (Fig. 767).

The anus is developed as a slight invagination of the epiblast a short distance

in front of the posterior end of the hind-gut. This invagination is termed the *proctodæum*; the mesoblast between it and the hypoblastic lining of the hind-gut is thinned, and ultimately the septum breaks down and disappears, and the hind-gut opens on the surface; into this part of the hind-gut the urinary and generative organs open for a time, and so it constitutes a *common cloaca*. The small portion of the hind-gut behind the orifice of the anus is named the *caudal* or *post-anal* gut; it communicates with the neural tube by means of a canal, the *neurenteric canal*, already referred to. Ultimately the post-anal gut becomes obliterated, and it, together with the neurenteric canal, finally disappears.

The peritoneal cavity is the space left between the visceral and parietal layers of the mesoblast, and the serous membrane is developed from these layers.

The tongue originates from the floor of the pharynx. The anterior or papillary portion first appears as a rounded elevation, the *tuberculum impar*, between the ventral ends of the mandibular and hyoid arches. Between the third and fourth arches a second larger elevation arises, in the centre of which is a median groove or furrow. This second elevation is termed the *furcula*, and from it the epiglottis is developed, while the median furrow becomes the entrance to the larynx (Fig. 771). The tuberculum impar and the furcula are at first in apposition, but are soon separated by a ridge produced by the forward growth of the second and third arches. This ridge gives rise to the posterior part of the tongue and extends forward in the form of a V, so as to embrace between its two limbs the tuberculum impar. At the apex of the V there is a pit-like invagination to form the middle thyroid rudiment, and this depression persists as the foramen cæcum of the adult. The union of the two parts of the tongue is indicated even

FIG. 766.—Final disposition of the intestines and their vascular relations. (Jonnescq.) A. Aorta. H. Hepatic artery. S. Splenic artery. M. Col. Branches of superior mesenteric artery. m, m'. Branches of inferior mesenteric artery.

FIG. 767.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)

in the adult by a V-shaped depression, the apex of which is at the foramen cæcum, while the two limbs run outward and forward parallel to but a little behind the circumvallate papillæ, which are therefore developed from the tuberculum impar (Figs. 772, 773). The tonsils are developed from the second branchial cleft, and make their appearance between the fourth and fifth months.

The *liver* arises in the form of two diverticula or hollow outgrowths from the ventral surface of that portion of the fore-gut which afterward becomes the

FIG. 768.—Schematic figure of the bursa omentalis, etc. Human embryo of eight weeks. (Kollmann.)

duodenum (Figs. 759, 760). The outgrowths, which represent the right and the left lobes, respectively, of the adult liver, give off solid buds of cells, which grow into columns or cylinders: these unite with one another in every direction to form a close network, in the meshes of which are contained the capillary blood-vessels. Some of these columns become hollowed out and form the bile-ducts, while the

FIG. 769.—Illustrating the development of the bursa omentalis, cavity of the great omentum or lesser sac. Foetal stage. * Lesser sac. (Hertwig.)

remainder constitute the secreting structure. The minute ducts thus produced unite to form the right and left hepatic ducts; while the common bile-duct is developed as a protrusion from the duodenal wall, and as it grows the liver becomes shifted away from the duodenum. The gall-bladder and cystic duct are formed by a hollow evagination from the wall of the common bile-duct. About the third month the liver almost fills the abdominal cavity. From this period the relative development of the liver is less active, more especially that of the left lobe, which

now becomes smaller than the right; but up to the end of foetal life the liver remains relatively larger than in the adult.

The *pancreas* is also an early formation, being far advanced in the second

FIG. 770.—Development of bursa omentalis. Infantile stage. Great omentum covers the intestines and has fused with the transverse mesocolon. Pancreas is free from peritoneum posteriorly. (Hertwig.)

month. It originates as a hollow projection from the hypoblast of the dorsal wall of the duodenum (Figs. 760 and 761), opposite the hepatic diverticula, which, as we have already seen, spring from its ventral wall. This hollow process grows

FIG. 771.—The floor of the pharynx of a human embryo about fifteen days old; $\times 50$. (From His.)

between the two layers of the dorsal mesentery and sends out offshoots, which branch abundantly and form a complicated tubular gland. As torsion of the stomach takes place, the pancreas assumes a transverse position and becomes fixed

FIG. 772.—The floor of the pharynx of a human embryo about twenty-three days old; $\times 30$. (From His.)

across the dorsal wall of the abdomen, the posterior layer of its mesentery undergoing absorption. Its duct ultimately opens into the duodenum together with the common bile-duct.

The *spleen*, on the other hand, is of mesoblastic origin, for there is never any

connection between the intestinal cavity and the substance of this organ. It originates in the mesenteric fold which connects the stomach to the vertebral column (mesogastrium) (Fig. 764).

The thyroid body is developed as a median and two lateral diverticula from the ventral wall of the pharynx. The median diverticulum appears first; it commences at the foramen cæcum, between the anterior and posterior rudiments of the tongue, and extends backward as a tubular duct, the *ductus thyro-glossus*. The lateral diverticula arise from the fourth visceral cleft and fuse with the median

FIG. 773.—Floor of mouth of an embryo slightly older than that shown in Fig. 772. $\times 16$. (From His.)

part to form the thyroid body. The connection of the lateral diverticula with the pharynx disappears early, but the remains of the ductus thyro-glossus may persist as a tube leading from the foramen cæcum toward the hyoid bone, the *pyramid* of the thyroid probably representing its lower part.¹

The thymus is developed from bilateral diverticula, which are principally derived from the third visceral cleft. It increases in size until the second year of life, after which it undergoes atrophy.

Development of the Respiratory Organs.—The lungs appear somewhat later than the liver. They are developed from a small median *cul-de-sac* or diverticulum from the upper part of the fore-gut, immediately behind the fourth visceral cleft. During the fourth week a pouch is formed on either side of the central diverticulum, and opens freely through it into the fore-gut (pharynx). These lateral pouches soon become subdivided—the right into three and the left into two parts, these subdivisions being the early indications of the lobes of the lungs (Figs. 716 and 761). The two primary pouches have thus a common tube of communication with the pharynx. This common tube becomes the larynx and trachea, the latter rapidly elongating as development proceeds. The larynx first becomes evident as a dilatation of the upper part of the trachea about the end of the fifth week. The epiglottis is developed from the anterior or median portion of the furcula, and the aryteno-epiglottidean folds from its lateral ridges (Fig. 772). The vocal cords and ventricles of the larynx are formed about the fourth month.

As the lungs grow backward they project into the anterior part of the cœlum, which becomes shut off from the rest of the body-cavity by the pericardium and Diaphragm to form the pleural cavities.

The Diaphragm is formed in two parts: (a) ventral, (b) dorsal. The ventral part appears first, and consists of a thick septum of mesoblast, the *septum transversum*, which projects from the anterior and lateral walls of the embryo, and which ends behind in a free edge. The sinus venosus, which receives the vitelline, umbilical, and Cuvierian veins is placed originally in this septum, and into the posterior part of it also the liver diverticula grow from the duodenum. The sinus separates itself above from the septum, and the greater part of it is incorporated with the right auricle. The liver also becomes separated from it below, except where the veins pass through into the heart. The septum transversum shuts

¹ Kanthack (*Journal of Anat. and Physiol.*, vol. xxv., p. 155) disputed this view. He examined 100 subjects, 60 of which were fetuses or infants, and found that in many cases there was no trace of foramen cæcum and that, when it was present, it formed a short canal near the surface and was lined with stratified squamous, not columnar, epithelium. Further, after careful microscopical examination he found no trace of a tubular lumen in the pyramid of the thyroid body.

off the greater part of the thoracic from the abdominal cavity, but posteriorly there remain two channels of communication, one on each side of the alimentary tube; these channels subsequently become the pleural cavities, and are shut off from the abdomen by folds which grow from the lateral and posterior parts of

FIG. 774.—Section of the urogenital area of a chick embryo of the fourth day. (Waldeyer.)

the trunk and which fuse with the posterior edge of the septum transversum. Sometimes the fusion is incomplete, thus leaving a permanent communication between the abdominal and one or other of the pleural cavities, and through which some of the abdominal contents may pass, forming what is termed a *diaphragmatic hernia*.

Development of the Urinary and Generative Organs.—The urinary organs are

FIG. 775.—Enlarged view from the front of the left Wolffian body before the establishment of the distinction of sex. (From Farre, after Kobelt.) *a, a, b, d*, Tubular structure of the Wolffian body; *e*, Wolffian duct; *f*, Its upper extremity; *g*, Its termination in *x*, the urogenital sinus; *h*, The duct of Müller; *i*, Its upper, funnel-shaped extremity; *k*, Its lower end, terminating in the urogenital sinus; *l*, The mass of blastema for the reproductive organ, ovary or testicle.

developed from a ridge of mesoblast at the point where this layer separates into somatopleure and splanchnopleure. As this ridge is situated close to the epiblast, between the paraxial mesoblast and the common pleuro-peritoneal cavity, it has been named the "intermediate cell-mass." It is at first solid, and in it is formed a cord-like arrangement of some of the cells, which extends longitudinally from just below the heart to the posterior extremity of the body-cavity. In this cord-like structure a tube is hollowed out; it gradually becomes separated from the rest of the intermediate cell-mass, and is then named the *Wolffian duct* (Fig. 700).¹ Its posterior end becomes connected with and eventually opens into the hind-gut. Its anterior end becomes connected with pit-like involutions of the peritoneal epithelium, and in the mesoblastic tissue between these invaginations a vascular glomerulus is formed which projects into the peritoneal cavity. It is known as the *head-kidney*

¹ By some embryologists the Wolffian duct is regarded as being of epiblastic origin and formed by a longitudinal invagination of the epiblast.

or *pronephros* (Lankester), and is a very rudimentary organ which speedily disappears. Behind this body and to the inner side of the Wolffian duct, between it and the body-cavity, a number of tubes are formed, which communicate by one extremity with the Wolffian duct, and, passing transversely toward the body-cavity, terminate in caecal extremities. These tubes are called segmental tubes, and the whole mass is known as the *mid-kidney*, *Wolffian body*, or *mesonephros* (Lankester) (Fig. 775). After a time the caecal extremities become dilated and enclose a tuft or glomerulus of capillary blood-vessels. As soon as the permanent kidneys are formed, the Wolffian body for the most part disappears. In the male, however, the vasa efferentia and rete testis of the testicle are formed as outgrowths from it. In the female traces of it are left as the *parovarium* and *epoöphoron*. In the male the Wolffian duct becomes the epididymis and vas deferens; in the female it undergoes atrophy, and is represented only by the functionless duct of Gärtner.

Finally, in that portion of the intermediate cell-mass which lies behind the Wolffian body, a differentiation of cells takes place which results in the formation of a number of convoluted tubes; into this a hollow protrusion of the lower end of the Wolffian duct grows up, and thus is formed the *hind-kidney* or *metanephros* (Lankester). This is the permanent kidney. The uriniferous convoluted tubes and Malpighian corpuscles are formed from the intermediate cell-mass, and the collecting tubules and ureter from the protrusion from the posterior end of the Wolffian duct.

Shortly after the formation of the Wolffian body, a second duct becomes developed. It arises on the outer side of this body as a slight thickening of the cells lining the pleuro-peritoneal cavity. This thickening then becomes invaginated into the mesoblast and extends as a cord along the outer side of the Wolffian body, to the posterior extremity of the embryo. It speedily acquires a lumen, and is then known as the *Müllerian duct* (Fig. 774).

In its passage to the posterior extremity of the embryo it comes into close relation with the Wolffian duct, and the two ducts on either side become connected with their fellows on the opposite side by their cellular substance into a single cord, the *genital cord* (Fig. 776, g, c), in which the Wolffian ducts lie side by side in front, and the ducts of Müller behind. These latter tubes in the substance of the genital cord become fused together, and open by a single orifice into the hind-gut (cloaca). At their anterior extremities the ducts of Müller open by a somewhat funnel-shaped orifice into the pleuro-peritoneal cavity. In the female the greater part of the Müllerian duct is developed into the Fallopian tube, but the posterior fused portion of the two ducts is converted into the uterus and vagina (Fig. 777). In the male the greater part of the ducts disappears; the posterior fused portion is believed to be represented by the *sinus pocularis* (*uterus masculinus*) of the urethra.

It has been seen that the Wolffian and Müllerian ducts open into the common cloaca, which is the termination of the intestinal cavity, and into which the allantois also opens in front (Fig. 776). As the allantois expands into the urinary bladder this common cavity

FIG. 776.—Diagram of the primitive urogenital organs in the embryo previous to sexual distinction. The parts are shown chiefly in profile, but the Müllerian and Wolffian ducts are seen from the front. 3. Ureter. 4. Urinary bladder. 5. Urachus. *ot*, The mass of blastema from which ovary or testicle is afterward formed; *W*, Left Wolffian body; *w, w*, Right and left Wolffian ducts; *m, m*, Right and left Müllerian ducts uniting together and with the Wolffian ducts in *gc*, the genital cord; *ug*, Sinus urogenitalis; *i*, Lower part of the intestine; *cl*, Common opening of the intestine and urogenital sinus; *cp*, Elevation which becomes clitoris or penis; *ls*, Ridge from which the labia majora or scrotum are formed.

is divided into two by a septum, to form the urogenital sinus in front and the

rectum behind, and the Wolffian and Müllerian ducts now open into the urogenital sinus.

The *urinary bladder*, as before stated, is formed by a dilatation of a part of the intra-embryonic portion of the allantois. At the end of the second month the middle part of this portion of the allantois becomes dilated into a spindle-shaped cavity, which persists as the *urinary bladder*. Between the lower extremity of the spindle-shaped dilatation and the intestine is the *urogenital sinus*, into which the Müllerian and Wolffian ducts now open, and which becomes the first part of the urethra. The upper part of the intra-embryonic portion of the allantois, which is not dilated, forms the *urachus* (Fig. 776); this extends into the umbilical cord, and at an early period of embryonic existence forms a tube of communication with the allantois. It is obliterated before the termination of foetal life, but the cord formed by its obliteration is perceptible throughout life, passing from the upper part of the bladder to the umbilicus. It occasionally remains patent after birth, constituting a well-known malformation.

The *suprarenal bodies* are developed from two different sources. The medullary part of the organ is of epiblastic origin, and is derived from the tissues forming the sympathetic ganglia of the abdomen, while the cortical portion is of mesoblastic origin, and originates as an outgrowth from the upper part of the Wolffian body. The two parts are at first quite distinct, but become combined in the process of development. The suprarenal capsules are at first larger than the kidneys; about the tenth week they equal them in size, and from that time decrease relatively to the kidney, though they remain, throughout foetal life, proportionally much larger than in the adult.

FIG. 777.—Female genital organs of the embryo, with the remains of the Wolffian bodies. (After J. Müller.) A. From a foetal sheep: a. The kidneys. b. The ureters. c. The ovaries. d. Remains of the Wolffian bodies. C. Still more advanced, from the human foetus of three months: a. The body of the uterus. b. The round ligament. c. The Fallopian tubes. d. The ovaries. e. Remains of the Wolffian bodies.

Ovaries and Testicles.—The first appearance of the reproductive organs is essentially the same in the two sexes, and consists in a thickening of the epithelial layer which lines the peritoneal or body-cavity close to the inner side of the Wolffian body. Beneath this thickened epithelium an increase in the mesoblast takes place, forming a distinct projection or ridge. This is termed the *genital ridge* (Fig. 774), and from it the testicle in the one sex, and the ovary in the other, are developed. As the embryo grows the genital ridge gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium*. About the seventh week the distinction of sex begins to be perceptible.

The ovary, thus formed from the genital ridge, consists of a central part of connective tissue covered by a layer or layers of epithelium, the *germinal epithelium*. Columns of this epithelium, termed *egg-tubes*, grow down into the stroma, and simultaneously with this an upward growth of the connective tissue takes place between the columns of epithelial cells. It results from this that the columns of cells become enclosed in meshes of connective tissue (Fig. 784). Each egg-tube or nest represents a primitive Graafian follicle, one cell of which becomes enlarged to form the ovum; the remainder form the epithelium of the follicle. The remains of the germinal epithelium on the surface of the ovary form the permanent epithelial covering of this organ. According to Beard, the primitive ova are early set apart during the segmentation of the ovum and migrate into the germinal ridge.

The testicle is developed in a very similar way to the ovary, but the processes are not so well marked. Like the ovary, in its earliest stages it consists of a central mass of connective tissue covered by germinal epithelium. A downward growth of columns of this epithelium into the central connective tissue takes place. From these the seminiferous tubules are developed and become connected with outgrowths from the Wolffian body, which, as before mentioned, form the rete testis and vasa efferentia.

With regard to the other parts of the internal female organs, the Fallopian tube, as has been mentioned, is developed from the upper part of the duct of Müller, while the lower parts of the two ducts approach each other, and, lying

FIG. 778.—Adult ovary, parovarium, and Fallopian tube. (From Farre, after Kobelt.) *a, a*, Epoöphoron formed from the upper part of the Wolffian body. *b*, Remains of the uppermost tubes sometimes forming hydatids. *c*, Middle set of tubes. *d*, Some lower atrophied tubes. *e*, Atrophied remains of the Wolffian duct. *f*, The terminal bulb or hydatid. *h*, The Fallopian tube, originally the duct of Müller. *i*, Hydatid attached to the extremity. *l*, The ovary.

side by side, finally coalesce to form the cavity of the uterus and vagina. This coalescence commences in the middle of the genital cord, and corresponds to the body of the uterus. With regard to the further changes in the female organs, the only remains of the Wolffian body in the complete condition are two rudimentary or vestigial structures, which can be found, on careful search, in the broad ligament near the ovary: the *parovarium* or *organ of Rosenmüller* and the *epoöphoron* (Fig. 778). The organ of Rosenmüller consists of a number of tubes which converge to a transverse portion, the epoöphoron, and this is sometimes prolonged into a distinct duct, running transversely, the *duct of Gärtner*, which is much more conspicuous and extends further in some of the lower animals. This, as has been pointed out, is the remains of the Wolffian duct. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The round ligament is derived from a band containing involuntary muscular fibres, which runs downward from the lower part of the Wolffian body to the groin, and which in

the male forms the gubernaculum testis; the peritoneum constitutes the broad ligament; the superior ligament of the Wolffian body, which serves to connect it with the Diaphragm, disappears with that body.

With regard to the other parts of the male organs, the Müllerian ducts disappear, with the exception of their lower ends. These unite in the middle line, and open by a common orifice into the urogenital sinus. This constitutes the *utriculus hominis* or *sinus prostaticus*. Frequently, however, the upper end of the duct of Müller remains visible in the male as a little pedunculated body, called the hydatid of Morgagni, in the neighborhood of the epididymis,¹ between the testis and globus major.

The epididymis, the vas deferens, and ejaculatory duct are formed from the Wolffian duct. One or more of the tubes of the Wolffian body form the vas aberrans and a structure described by Giralès, and called, after him, "the organ of Giralès," which bears some resemblance to the organ of Rosenmüller in the other sex. It consists of a number of convoluted tubules, lying in the cellular tissue in front of the cord, and close to the head of the epididymis.

Descent of the Testes.—The testes, at an early period of fetal life, are placed at the back part of the abdominal cavity, behind the peritoneum and a little below the kidneys. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the *gubernaculum testis*, makes its appearance. This structure is at first a slender band, extending

FIG. 779.—Section of the ovary of a newly born child. (Waldeyer.)

from that part of the skin of the groin which afterward forms the scrotum through the inguinal canal to the body and epididymis of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the *mesorchium*, which also encloses the gubernaculum and forms two folds, one above the testicle and the other below it. The one above the testicle is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the *processus vaginalis*, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, while the upper part has disappeared. The lower part can now be seen to consist of a central core of unstriped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. As the scrotum

¹ Mr. Osborn, in the *St. Thomas's Hospital Reports*, 1875, has written an interesting paper pointing out the probable connection between this fetal structure and one form of hydrocele.

develops, the lower end of the gubernaculum is carried with the skin to which it is attached to the bottom of this pouch. The fold of peritoneum, constituting the processus vaginalis, projects itself downward into the inguinal canal, and emerges at the external abdominal ring, pushing before it a part of the internal oblique muscle and the aponeurosis of the external oblique, which form, respectively, the cremaster muscle and the external spermatic fascia. It forms a gradually elongating depression or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and into this the testicle is drawn by the growth of the body of the fœtus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the bottom grows, and is drawn first into the inguinal canal and eventually into the scrotum. It seems certain also that the gubernacular cord becomes shortened as development proceeds, and this assists in causing the testicle to reach the bottom of the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is now entirely cut off from the general peritoneal cavity, constitutes the *tunica vaginalis*.¹

In the female there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive a change as that of the testicle in the male. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus formed by the union of the Müllerian ducts, contracts adhesions to this organ, and thus the ovary is prevented from descending below this level. The remains of the gubernaculum—that is to say, the part below the attachment of the cord to the uterus to its termination in the labia majora—ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male; it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labia majora, extending down the canal of Nuck, and under these circumstances resembles in position the testicles in the male.

Surgical Anatomy.—Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed; or the testicle may be fully developed, and the vas deferens may be undeveloped in whole or part; or, again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent, or it may descend into some abnormal position. Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position: it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. There is still a third class of cases of abnormality of the testicle: where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testicle is *inverted*; that is to say, the organ is rotated so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hæmatocele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be *reversed*. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ. Cases sometimes occur, generally in the young adult, in which the spermatic cord becomes twisted. In consequence of this the circulation through it is partially or completely arrested; if the latter, the testicle becomes gangrenous; if the former, it may undergo atrophy.

The external organs of generation (Fig. 780), like the internal, pass through

¹ The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete. See section on Inguinal Hernia.

a stage in which there is no distinction of sex. It is therefore necessary to describe this stage, and then follow the development of the female and male organs respectively.

As stated above, the anal depression, or proctodæum, at an early period is formed by an involution of the epiblast, and the intestine is still closed at its lower end. When the septum between the two opens, which is about the fourth week, the urachus in front and the intestine behind both communicate with the anal

FIG. 780.—Stages in the development of the external sexual organs in the male and female. (After the Ecker-Ziegler wax models.) (From Hertwig's *Entwicklungsgeschichte*.)

depression. This, which is now called the *cloaca*, is afterward divided by a transverse septum, the *perineum*, which appears about the second month. Two tubes are thus formed: the posterior becomes the lower part of the rectum, the anterior is the urogenital sinus. In the sixth week a tubercle, the *genital eminence*, is formed in front of the cloaca, and this is soon surrounded by two folds of skin, the *genital ridges*. Toward the end of the second month the genital tubercle presents, on its lower aspect, a groove, the *genital groove*, which extends downward toward the cloaca. This groove becomes deeper, and is bounded laterally by projecting folds of skin, the *genital folds*. All these parts are well developed by the second month, yet no distinction of sex is possible.

Female Organs.—The female organs are developed by an easy transition from the above. The urogenital sinus persists as the vestibule of the vagina and the urethra. The genital eminence forms the clitoris, the genital ridges the labia majora, and the lips of the genital groove the labia minora, which remain open. An innovation of the epithelium takes place on either side close to the root of the genital tubercle, which becomes the glands of Bartholin.

Male Organs.—In the male the changes are greater. The genital eminence is developed into the penis, the glans appearing in the third month, the prepuce and corpora cavernosa in the fourth. The genital groove closes and thus forms a canal, the spongy portion of the urethra. The urogenital sinus becomes elongated and forms the membranous urethra. The genital ridges unite in the middle line to form the scrotum, at about the same time as the genital groove closes, viz.,

between the third and fourth month. A similar involution of epithelium to that which in the female forms the glands of Bartholin takes place in the male and becomes the glands of Cowper.

The following table is translated from the work of Beaunis and Bouchard, with some alterations, especially in the earlier weeks. It will serve to present a *résumé* of the above facts in an easily accessible form.¹

¹ It will be noticed that the time assigned in this table for the appearance of the first rudiment of some of the bones varies in some cases from that assigned in the description of the various bones in the sequel. This is a point on which anatomists differ, and which probably varies in different cases.

CHRONOLOGICAL TABLE

OF

THE DEVELOPMENT OF THE FŒTUS.

(FROM BEAUNIS AND BOUCHARD.)

First Week.—During this period the ovum is in the Fallopian tube. Having been fertilized in the upper part of the tube, it slowly passes down, undergoing segmentation, and reaches the uterus probably about the end of the first week. During this time it does not undergo much increase in size.

Second Week.—The ovum rapidly increases in size and becomes imbedded in the decidua, so that it is completely enclosed in the decidua reflexa by the end of this period. An ovum believed to be of the thirteenth day after conception is described by Reichert. There was no appearance of any embryonic structure. The equatorial margins of the ovum were beset with villi, but the surface in contact with the uterine wall and the one opposite to it were bare. In another ovum, described by His, believed to be of about the fourteenth day, there was a distinct indication of an embryo. There was a medullary groove bounded by folds. In front of this a slightly prominent ridge, the rudimentary heart. The amnion was formed and the embryo was attached by a stalk, the allantois, to the inner surface of the chorion. It may be said, therefore, that these parts, the amnion and the allantois, and the first rudiments of the embryo, the medullary groove, and the heart, are formed at the end of the second week.

Third Week.—By the end of the third week the flexures of the embryo have taken place, so that it is strongly curved. The protovertebral disks, which begin to be formed early in the third week, present their full complement. In the nervous system the primary divisions of the brain are visible, and the primitive ocular and auditory vesicles are already formed. The primary circulation is established. The alimentary canal presents a straight tube communicating with the yolk-sac. The branchial arches are formed. The limbs have appeared as short buds. The Wolffian bodies are visible.

Fourth Week.—The umbilical vesicle has attained its full development. The caudal extremity projects. The upper and the lower limbs and the cloacal aperture appear. The heart separates into a right and left heart. The special ganglia and anterior roots of the spinal nerves, the olfactory fossæ, the lungs and the pancreas can be made out.

Fifth Week.—The allantois is vascular in its whole extent. The first traces of the hands and feet can be seen. The primitive aorta divides into aorta and pulmonary artery. The duct of Müller and genital gland are visible. The ossification of the clavicle and the lower jaw commences. The cartilage of Meckel occupies the first post-oral arch.

Sixth Week.—The activity of the umbilical vesicle ceases. The pharyngeal clefts disappear. The vertebral column, primitive cranium, and ribs assume the cartilaginous condition. The posterior roots of the nerves, the membranes of the nervous centres, the bladder, kidney, tongue, larynx, thyroid body, the germs of teeth, and the genital tubercle and folds are apparent.

Seventh Week.—The muscles begin to be perceptible. The points of ossification of the ribs, scapula, shaft of humerus, femur, tibia, palate, and upper jaw appear.

Eighth Week.—The distinction of arm and forearm, and of thigh and leg, is apparent, as well as the interdigital clefts. The capsule of the lens and pupillary membrane, the interventricular and commencement of the interauricular septum, the salivary glands, the spleen, and suprarenal capsules are distinguishable. The larynx begins to become cartilaginous. All the vertebral bodies are cartilaginous. The points of ossification for the ulna, radius, fibula, and ilium make their appearance. The two halves of the hard palate unite. The sympathetic nerves are now for the first time to be discerned.

¹ [Eternod (*Anat. Anzeiger*, Band xv., 1898) described an ovum which he reconstructed. It had a precise history, from which he concluded that it must have belonged to the end of the second or the beginning of the third week. Including the villi it measured $10 \times 8.2 \times 6$ mm. It was flattened on its embryonal side, and the embryo measured 1.3 mm. The amnion was completely formed and the allantois existed as a long canal. The vitelline circulation was established and the villi of the chorion were beginning to be vascularized. The blastopore still opened into the amniotic cavity, with the primitive groove behind it and the rudimentary groove in front. The notochord was closing in and all three layers of the blastoderm were distinct, except around the blastopore, where they formed an undivided mass.—EDS.]

Ninth Week.—The corpus striatum and the pericardium are first apparent. The ovary and testicle can be distinguished from each other. The genital furrow appears. The osseous nuclei of the bodies and arches of the vertebræ, of the frontal, vomer, and malar bones of the shafts of the metacarpal and metatarsal bones, and of the phalanges appear. The union of the hard palate is completed. The gall-bladder is seen.

Third Month.—The formation of the foetal placenta advances rapidly. The projection of the caudal extremity disappears. It is possible to distinguish the male and female organs from each other. The cloacal aperture is divided into two parts. The cartilaginous arches on the dorsal region of the spine close. The points of ossification for the occipital, sphenoid, lachrymal, nasal, squamous portion of temporal and ischium appear, as well as the orbital centre of the superior maxillary. The pons Varolii and fissure of Sylvius can be made out. The eyelids, the hair, and the nails begin to form. The mammary gland, the epiglottis, and prostate are beginning to develop. The union of the testicle with the canals of the Wolffian body takes place.

Fourth Month.—The closure of the cartilaginous arches of the spine is complete. Osseous points for the first sacral vertebra and os pubis appear. The ossification of the malleus and incus takes place. The corpus callosum, the membrana lamina spiralis, the cartilage of the Eustachian tube, and the tympanic ring are seen. Fat is first developed in the subcutaneous cellular tissue. The tonsils are seen, and the closure of the genital furrow and the formation of the scrotum and prepuce take place.

Fifth Month.—The two layers of the decidua begin to coalesce. Osseous nuclei of the axis and odontoid process, of the lateral points of the first sacral vertebra, of the median points of the second, and of the lateral masses of the ethmoid make their appearance. Ossification of the stapes and the petrous bone and ossification of the germs of the teeth take place. The germs of the permanent teeth and the organ of Corti appear. The eruption of hair on the head commences. The sudoriferous glands, Brunner's glands, the follicles of the tonsil and base of the tongue, and the lymphatic glands appear at this period. The differentiation between the uterus and vagina becomes apparent.

Sixth Month.—The points of ossification for the anterior root of the transverse process of the seventh cervical vertebra, the lateral points of the second sacral vertebra, the median points of the third, the manubrium sterni and the os calcis appear. The sacro-vertebral angle forms. The cerebral hemispheres cover the cerebellum. The papillæ of the skin, the sebaceous glands, and Peyer's patches make their appearance. The free border of the nail projects from the corium of the dermis. The walls of the uterus thicken.

Seventh Month.—The additional points of the first sacral vertebra, the lateral points of the third, the median point of the fourth, the first osseous point of the body of the sternum, and the osseous point for the astragalus appear. Meckel's cartilage disappears. The cerebral convolutions, the island of Reil, and the tubercula quadrigemina are apparent. The pupillary membrane atrophies. The testicle passes into the vaginal process of the peritoneum.

Eighth Month.—Additional points for the second sacral vertebra, lateral points for the fourth and median points for the fifth sacral vertebra, can be seen.

Ninth Month.—Additional points for the third sacral vertebra, lateral points for the fifth, osseous points for the middle turbinated bone, for the body and great cornu of the hyoid, for the second and third pieces of the body of the sternum, and for the lower end of the femur appear. Ossification of the bony lamina spiralis and axis of the cochlea takes place. The eyelids open, and the testicles are in the scrotum.
